Table 5.82. Water quality measurements at Site 6, Rio Grande near San Antonio, New Mexico, during July 2008. [Temperature (C), water temperature in Celsius; SpCond (uS/cm), specific conductivity in microSiemens per centimeter; pH in standard units; DO (mg/L), dissolved oxygen in milligrams/Liter; DO Saturation (%), percent saturation dissolved oxygen; *, probe likely buried or repositioned; gray shading identifies time between dusk to dawn (see narrative text for more information).]

Table 6. Summary statistics for water temperature measurements by sample year, date of deployment, season, and site listed from upstream to downstream. [Water temperature in Celsius; N, number of observations; Std. Dev., standard deviation. See narrative text for information on device name. "Nike," "Athena," and "Apollo" are Troll 9500s by In-Situ, Inc.; "Hermes," "Homer," "Marge," and "Phoebe" are Sondes by Hydrolab, Inc. Water temperature values were censored when probes were considered covered with sediment (i.e., identified by less than 50 percent oxygen saturation)].

Table 7. Summary statistics for specific conductivity measurements by sample year, date of deployment, season, and site listed from upstream to downstream. [Specific conductance in microsiemens per centimeter at 25°C; N, number of observations; Min, minimum; Max, maximum; Std.Dev., standard deviation; Var., variatiance. See narrative text for information on device name. "Nike," "Athena," and "Apollo" are Troll 9500s by In-Situ, Inc. did not measure conductance; "Hermes," "Homer," "Marge," and "Phoebe" are Sondes by Hydrolab, Inc. Specific conductivity values were censored when probes were considered covered with sediment (i.e., identified by less than 50 percent oxygen saturation)].

Table 8. Summary statistics for pH measurements by sample year, date of deployment, season, and site listed from upstream to downstream. ["pH" is the negative base 10 logarithm of the molar activity of dissolved hydrogen ions (H+) and a measure of acidity or basicity; N, number of observations; Min, minimum; Max, maximum; Std.Dev., standard deviation; Var., variation. "Nike," "Athena," and "Apollo" are Troll 9500s by In-Situ, Inc. and did not measure pH; "Hermes," "Homer," "Marge," and "Phoebe" are Sondes by Hydrolab, Inc. pH values were censored when probes were considered covered with sediment (i.e., identified by less than 50 percent oxygen saturation)].

Table 9. Summary statistics for oxygen dissolved in water by sample year, date of deployment, season, and site listed from upstream to downstream. [Dissolved oxygen in mg/L; N, number of observations; Min, minimum; Max, maximum; Std.Dev., standard deviation; Var., variation. See narrative text for information on device name. "Nike," "Athena," and "Apollo" are Troll 9500s by In-Situ, Inc. and used optical sensors; "Hermes," "Homer," "Marge," and "Phoebe" are Sondes by Hydrolab, Inc. and used membrane electrodes. Dissolved oxygen values were censored when probes were considered covered with sediment (i.e., identified by less than 50 percent oxygen saturation)]

Chapter 2. Rio Grande Silvery Minnow Health Assessment

Report prepared by

Anne P. Davis and Joel D. Lusk

U.S. Fish and Wildlife Service
New Mexico Ecological Services Field Office
2105 Osuna Road NE
Albuquerque, NM 87113

Funded by the Middle Rio Grande Endangered Species Act Collaborative Program through U.S. Bureau of Reclamation Interagency Agreement Number 06-AA-40-2548.
Cover photography by A.Davis/USFWS: 1) Severely eroded caudal fin; 2) anal fin lesion; and, 3) 50 percent mesenteric fat condition in Rio Grande silvery minnow.

December 2012

INTRODUCTION

Fish health assessments are a standard system of observation of fish tissues and organs and measurements during a necropsy that are based methods reported by Goede and Barton (1990), Schmitt et al. (1999), Schmitt and Dethloff (2000), and others. We collected Rio Grande silvery minnow (*Hybognathus amarus*; silvery minnow) at six locations (Table 1) within the Middle Rio Grande (MRG) during July 2006 to April 2007 (Year 1) and October 2007 to July 2008 (Year 2) (Lusk 2012a) for health assessments. We generated a Health Assessment Index (HAI) that was used as a general indicator of fish health (Carlander 1969, 1977; Adams 1990). The HAI utilizes observations of gross external and internal pathological disorders and scoring procedures to rank relative health (Goede 1988, 1989, 1996; Adams et al. 1993). Developed and revised by Goede (1988, 1989, 1996), Adams et al. (1993), and others, this systematic observation and necropsy has been used by scientists in field and hatchery situations (Schmitt et al. 1999; Schmitt and Dethloff 2000) as well as on fish collected from the Rio Grande (Abeyta and Lusk 2004a citing Sykes 2003; Schmitt et al. 2004, 2005, Papoulias et al. 2008). These and similar fish health indices can signify overall health status of the subpopulation sampled. Fish health indices can also be used to reflect the status of organ systems or feeding, which may change due to environmental factors or other stressors (Schmitt et al. 1999).

Review of Fish Health Studies conducted in the Middle Rio Grande

During 1993 to 1995, Carter (1997a, 1997b) used fish health monitoring and assessments to characterize water quality in the Rio Grande. Carter (1997a) reported that the occurrence of anomalies in the fish they collected was less than 2 percent, while fish collected from the Rio Grande near Isleta, New Mexico, had anomaly rates as high as 14 percent. Carter (1997a) concluded that the high percentages of introduced species, the dominance of omnivorous species, and the high incidence of anomalies were indicative of a fish community under chronic stress at the Isleta, New Mexico, location.

During 1997 to 1999, the Service conducted the National Wild Fish Health Survey, which included surveys of pathogens and parasites of silvery minnow and other minnows collected from the Rio Grande. No interpretative report on the pathogen data from Rio Grande fish was published (Knapp and Mueller 2004), however, those fish health observations are available from the National Wild Fish Health Survey Database (available at http://www.fws.gov/wildfishsurvey/database/).

During 1997 and 1998, Schmitt et al. (2004) collected, examined, and analyzed large fish from 10 sites on tributary rivers of the Rio Grande to document temporal and geographic trends in the concentrations of contaminants and to assess contaminant effects on the fish. Schmitt et al. (2004) noted a minimal number of altered biomarkers and few or no elevated contaminant concentrations in fish tissues from their upper Rio Grande sites. However, hepatic activity in some fish was seen as elevated and may have reflected exposure to polycyclic aromatic hydrocarbons (Schmitt et al. 2004).

During 2002 and 2003, Sykes (2003) and Abeyta and Lusk (2004a, 2004b), used fish health assessments of minnows to help characterize the water quality conditions in the MRG. Over 60 percent of the fish observed had shortened opercula and they suggested both environmental and nutritional components to those conditions (Abeyta and Lusk 2004b; Sykes 2003). Minnows that were collected in the winter appeared to be in better condition and feeding more actively than fish collected in the summer or fall (Sykes 2003). However, fish health sampling was too sparse to make definitive conclusions about site or seasonal differences (Sykes 2003). Abeyta and Lusk (2004b) reported a relationship, albeit weak, between whole stream metabolism and several fish health condition indices, suggesting that oxygen dynamics, specifically its overall production and consumption, may have played a role in the health of the minnow community.

In 2005, river intermittency isolated silvery minnows in large pools throughout several miles of the MRG (Caldwell 2005). During this time, silvery minnows were rescued from pools and transported to Dexter Fish Health Unit for examination. Of the fish examined, gill tissues were found to be infested with parasites and kidney tissues were infected with bacteria (P. Hines, Service, written comm. October 13, 2005). The silvery minnows collected from these intermittent pools were considered to be in poor health and moribund. When fish are healthy, both the fish and its protozoan parasites can exist in a symbiotic relationship (Caldwell 2005). However, when fish become stressed, and are in poor health or moribund, this relationship may change quickly to pathogenic (Caldwell 2005). If the environmental conditions change to favor the reproductive potential of protozoan parasites and bacteria (e.g., increased water temperature) or environmental conditions stress fish or compromise their immune system (e.g., low dissolved oxygen, crowding, elevated blood cortisol, elevated ammonia, poor nutritional status, etc.), then the rapid reproduction of these pathogens or increase in the susceptibility of the fish to disease can result in fish mortalities (Caldwell 2005 citing Post 1983).

During 2006, common carp (*Cyprinus carpio*), channel catfish (*Ictalurus punctatus*), and white sucker (*Catostomus commersoni*) samples were taken from the MRG and evaluated for fish health condition (Papoulias et al. 2008). Fish collected near Socorro, New Mexico, had elevated macrophage aggregates (both number and size), elevated vitellogenin concentrations (i.e., egg protein precursors) in male catfish similar to concentrations of vitellogenin levels found in reproductive females, and possibly elevated reproductive hormones. Papoulias et al. (2008) reported that MRG fish had mild to moderate pathological lesions and suggested that the existing environmental conditions may be stressing fish. However, Papoulias et al. (2008) noted that greater numbers of observations would be required to ascertain if elevated vitellogenin levels in MRG fish were related to reproductive stressors or endocrine disrupting chemicals.

During 2006 to 2007, Caldwell et al. (2010) assessed the physiological stress response of rescue practices and river intermittency by measuring changes in blood chemistry and parasite and bacterial burdens in wild silvery minnows and compared those responses to those in silvery minnows collected from a perennial reach (i.e., flowing water) and subjected to similar collection and transport activities. The cumulative effects of intermittency followed by capture and transport resulted in a greater magnitude of

physiological stress response in silvery minnows. The cumulative effects of intermittency as well as exposure within isolated pools elevated the silvery minnow stress response and increased their susceptibility to opportunistic pathogens and mortality.

During Fall 2007, Buhl (2011) exposed silvery minnows in cages at three site treatments in the MRG for 26 days to evaluate their survival, growth, and overall health conditions. Buhl (2011) used a necropsy-based health assessment to characterize and compare the health status of silvery minnows prior to and after in-situ exposures to the site waters. The most common anomalies observed by Buhl (2011) were shortened opercula (96 percent of fish, all rated as slightly shortened) and fin anomalies (attributed to cage artifacts). During the 26-day exposures, the health of the fish deteriorated significantly as evidenced by higher proportions of fish with abnormal fins and the presence of parasites. Tissue collected for histopathological examination revealed numerous macrophage aggregates in ovaries (92 percent), spleen (91 percent), and kidney (74 percent) with a lower prevalence in the testes (20 percent) and liver (15 percent). According to Buhl (2011), fish that are chronically stressed, in poor health, chronically exposed to environmental pollution, or have nutritional deficiencies may tend to have more and larger macrophage aggregates in their tissues. However, the prevalence of macrophage aggregates in silvery minnow tissues exposed to site treatments for 26 days, did not differ statistically among sites, gender, or from those in fish sampled prior to the treatments.

In summary, fish health assessments conducted on fish from the Middle Rio Grande have often observed shortened opercula, and numerous individuals have been reported with health indices that indicated chronic stress, and particularly, the stress of intermittency, which often results in poor health conditions and high parasite loads contributing to the mortality of silvery minnows. Site differences in health conditions were inconclusive or varied by study. Seasonal differences, where observed, suggested fish health conditions declined in summer and improved in winter. Several fish health studies have identified elevated macrophage aggregates in various tissues in fish collected from the Middle Rio Grande. Macrophage aggregates are focal accumulations of immune cells in tissues that, when elevated, are useful for discriminating between fish exposed to degraded water quality conditions. Fish health assessments conducted in the Middle Rio Grande have linked the condition of intermittency and subsequent isolation of fish in pools with degraded water quality and poor silvery minnow health conditions.

METHODS

A maximum of 30 silvery minnows were collected from each of the six sites sampled during two sample years (during July 2006 to April 2007 (Year 1) and October 2007 to July 2008 (Year 2)) for our fish health assessment (Table 1). Lusk (2012a) described the methods of site selection, collection locations, and transport of silvery minnows used in this fish health assessment. Silvery minnows were individually observed, measured, and processed within several hours after capture so that their condition would be representative of site conditions. Silvery minnows were observed using a digital stereomicroscope (Leica Model GZ6 stereomicroscope). Organ conditions and any anomalies were documented photographically using an attached Optronics MagnaFire SP digital camera. A Mettler Toledo balance (Model PR803) was used for mass measurements. The balance was routinely calibrated and checked against known standards. It was accurate to 0.001 g and had a 810 g maximum capacity.

Fish Health Observations and Necropsy Methods

Silvery minnows were subdued and examined using methods described by (Schmitt et al. 1999) as modified below. All observations of external and internal organ condition were recorded on the Fish Health Examination Sheet (Appendix 2A) for each individual silvery minnow observed. All silvery minnows were individually measured for weight (mass in grams [g]) and total length (TL). Total length was determined by laying the succumbed silvery minnow on a ruler marked in millimeters (mm). External examination began with the observation of the head, eyes, and body surface for anomalies. Anomalies in fish tissues and organs are deviations from those normally observed (Schmitt et al. 1999). Anomalies observed may include lesions, tumors, skeletal deformities, gill or fin fraying and erosion, hemorrhagic tissues, parasites, and other grossly observable conditions (Schmitt et al. 1999). Gills were examined for clubbing, fraying, pale coloring, margination, and parasites. Opercula were examined for shortening or deformity (described below). Fins were examined for fraying, erosion, hemorrhaging, and parasites. Fins were observed individually and their overall conditions were analyzed collectively. Examples of several external anomalies we observed in silvery minnows are provided in Figure 1 through Figure 4.

Observation of Silvery Minnow Opercula

We refer to opercula (also opercles, or singular, operculum) as they include the entire morphological structure, or opercular complex, of bone, skin, and collagen. The degree of shortening was noted as slight or severe (Figure 2). Generally, shortened opercula were identified when the skin, cartilage or bone was reduced from its full extent or deformed as viewed in profile. Slight shortening is described as visible shortening with flap obviously not covering entire gill (Figure 2A), and with minimal amount of gill exposed. Severe shortening is described as extreme shortening with much of the gill exposed and visible to the naked eye (Figure 2B). For evaluation, shortened opercula were analyzed as present/absent rather than according to the degree of shortening to reduce the subjective nature of the shortened opercula observations.

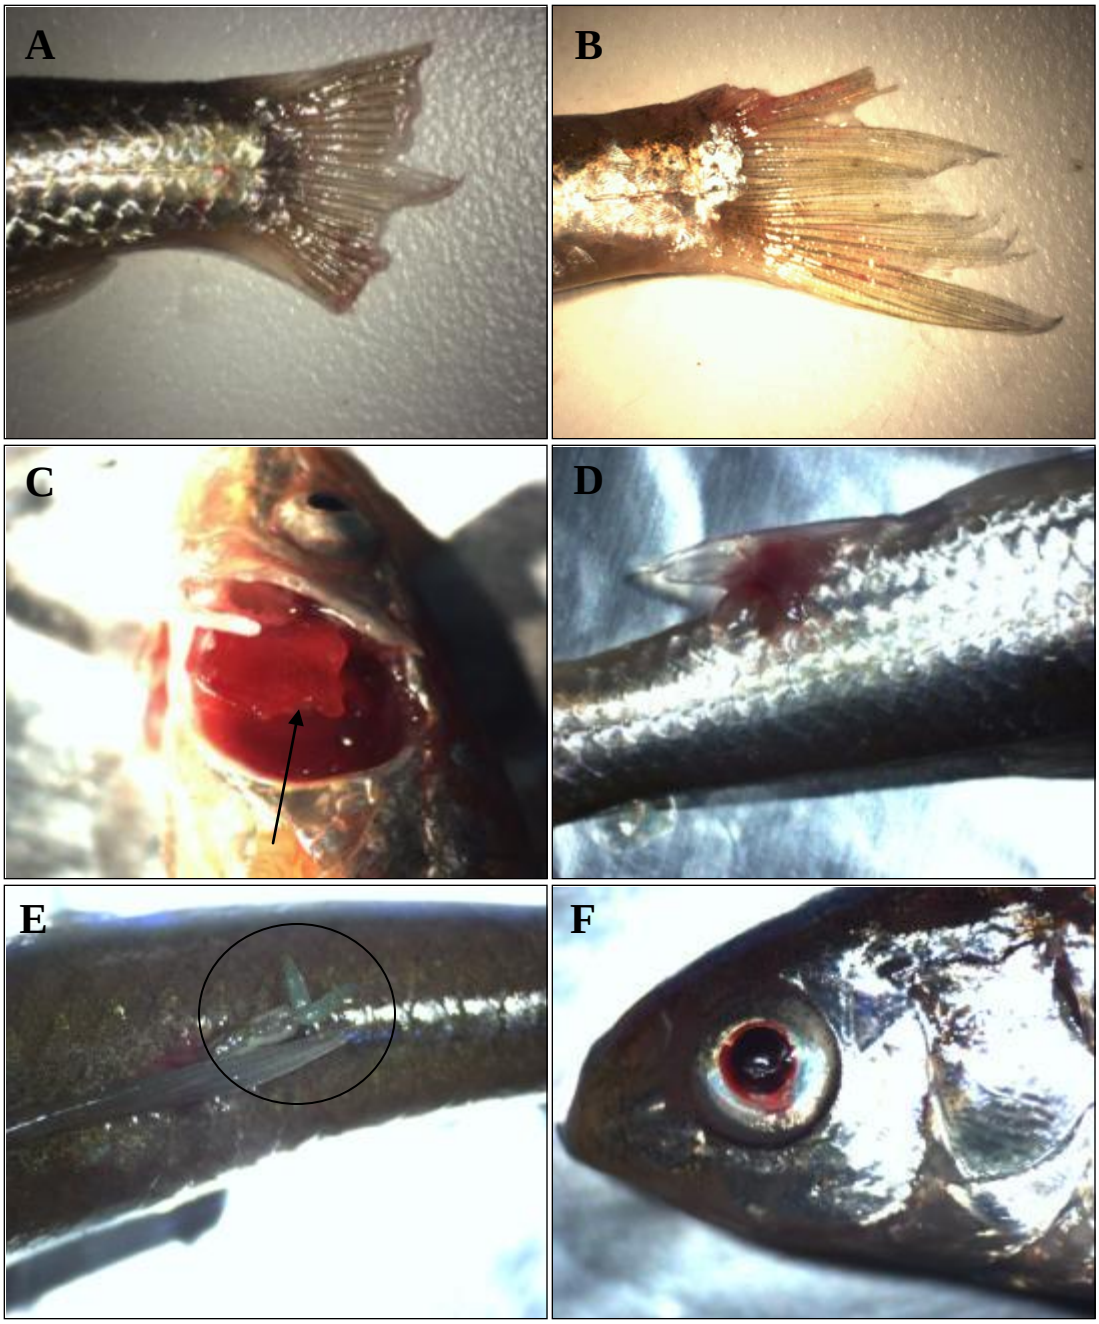

Figure 1. Examples of external anomalies: (A) severe fin erosion; (B) fin erosion and fraying; (C) frayed gill; (D) skin lesion; (E) parasites; and (F) hemorrhagic eye. All photography by A. Davis/USFWS.

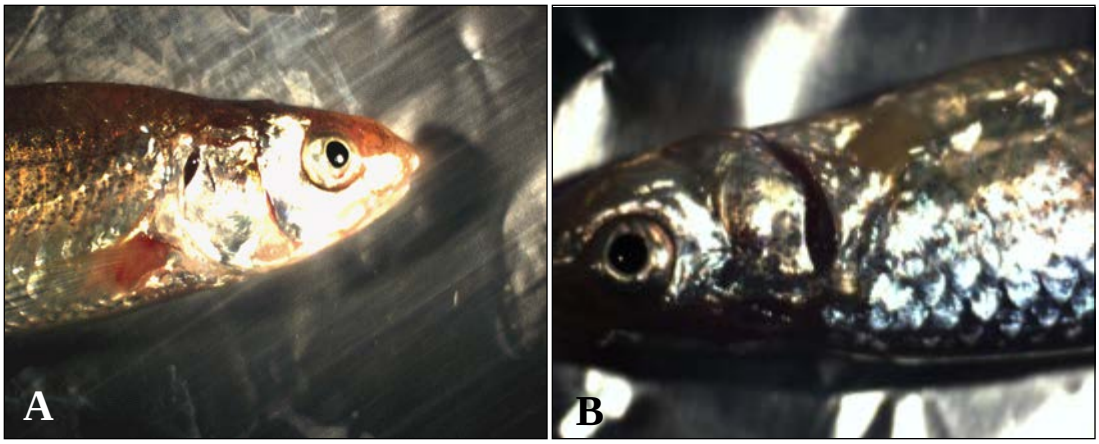

Figure 2. Slight opercula shortening (A); and severe opercula shortening (B).

Once the external examination was complete, silvery minnows were dissected using surgical scalpels, forceps, and other tools, and the viscera were removed onto foil. Forceps, foil, and other instruments used during the necropsy were rinsed with acetone and deionized water between fish to reduce cross contamination. We examined the viscera and internal organs to observe tumors or nodules, inflammation, hemorrhaging, or discoloration. The liver was observed for discoloration and condition. As cyprinid livers tend to be made up of dispersed nodules (Schmitt and Dethloff 2000), silvery minnow livers were not extracted from the viscera and weighed. The gall bladder was observed for fullness and color. The spleen was examined for color, granular texture, nodules, and enlargement. The spleen was removed from the viscera and its weight was measured on a mass balance. The amount of mesenteric fat was qualitatively observed. The kidneys were examined for color, swelling, urolithiasis (i.e., "stones"), or nodules. Gender, to the extent determinable, was verified upon internal examination (Figure 3). Gonads were removed and preserved separately in vials containing 10 percent, neutral buffered formalin, for histopathological verification, as necessary.

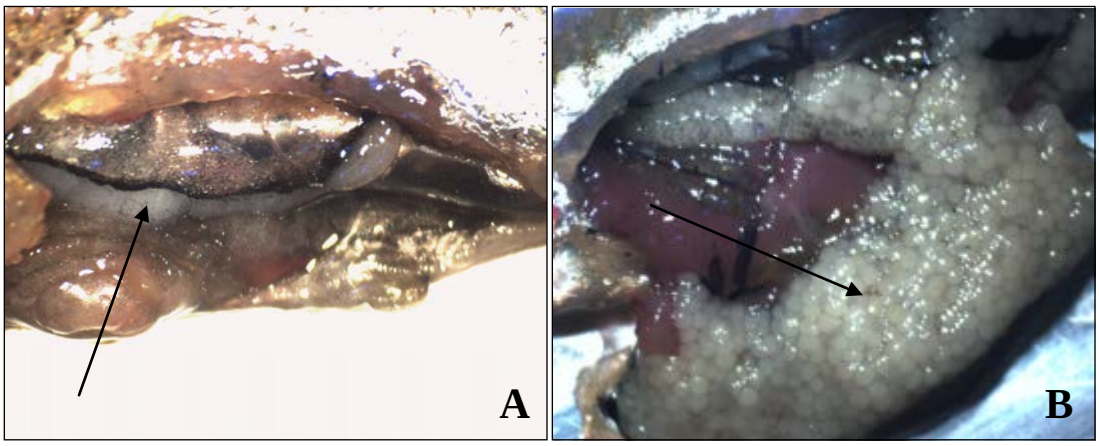

Figure 3. Examples of (A) male gonads; and, (B) female gonads.

Examples of several internal anomalies we observed in silvery minnows are provided in Figure 4. As necessary, grossly abnormal tissues were collected, noted, and stored for further histopathological examination. After examination, viscera, including organs and tissues examined, except gonads, were placed back into the carcass. The carcass was wrapped in foil, frozen (4 °C), and later used for chemical analyses (see Lusk 2012b).

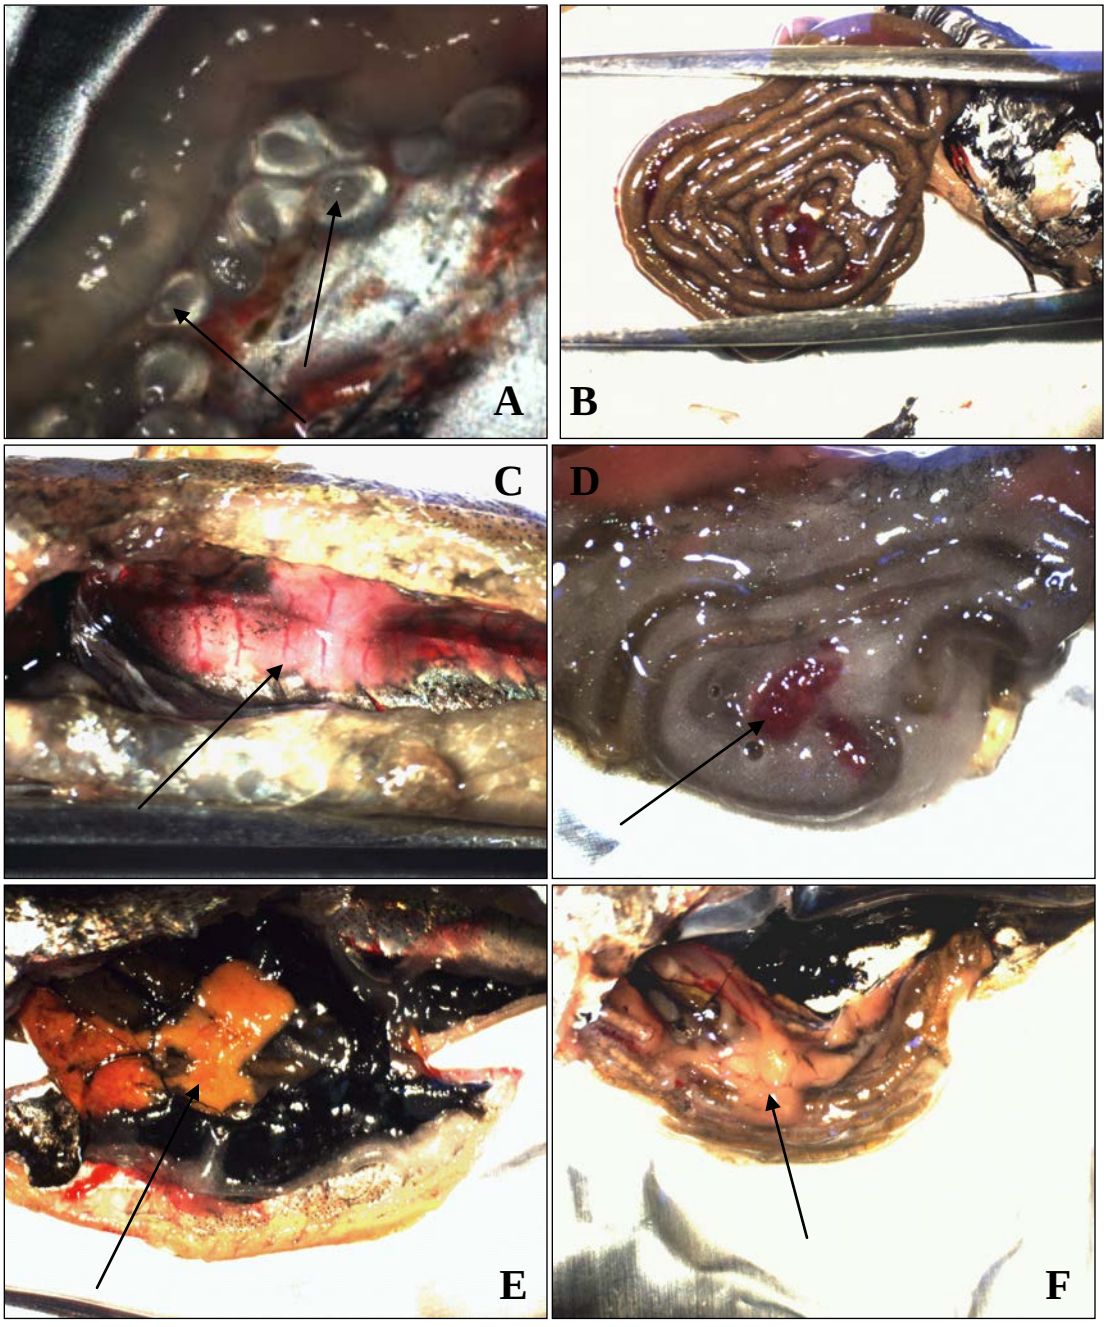

Figure 4. Examples of internal anomalies: (A) parasites in the mesentery; (B) full gut; (C) swollen kidney; (D) nodular spleen; (E) discolored liver; and (F) tan (fatty) liver.

Sampling Silvery Minnow Tissues for Histopathology

From the silvery minnows examined from each site, several individuals were randomly preselected for further histopathological examination by the U.S. Geological Survey's (USGS) Columbia Environmental Research Center (CERC), in Columbia, Missouri (see Papoulias et al. 2009). These silvery minnow tissues were termed Histopath Samples. During external and internal examinations of these preselected silvery minnows, any grossly abnormal tissues, as well as samples of the liver, gonad, spleen, and kidney were removed with forceps and preserved in a labeled, 2-milliliter (mL), polypropylene vial with polyethylene screw caps (e.g., Cryovial) partially filled with 10 percent, neutral buffered formalin.

During Year 1, ten percent of the silvery minnows necropsied were preselected as Histopath Samples. During Year 2, we increased the number of Histopath Samples to 20 percent. Additionally, during Year 2, after necropsy, entire silvery minnow bodies were preserved and shipped for histopathological examination, instead of individual organs and tissues. All Histopath Samples were sent preserved in buffered formalin to the USGS CERC for further observation, histology, histopathology, and analyses. Their analyses included microscopic examination of the tissues for the presence of lesions, observations of macrophage aggregates (MA) in spleen and kidney tissues, and examination of gonads to determine gender and reproductive stage among other measurements and evaluations (see Papoulias et al. 2009).

Calculation of the Health Assessment Index and other Indices

The splenosomatic index (SSI) was calculated as the percentage of the spleen weight to total body weight (Busacker et al. 1990). The HAI was calculated using the observations of gross external and internal anomalies as a general indicator of silvery minnow health during this study. The HAI can be a valuable method for estimating cumulative stress, and documenting lesions or anomalies that have advanced to the point of being grossly visible, those the public are often most concerned about (Adams et al. 1992; Schmitt and Dethloff 2000). Following Adams et al. (1992), we used a numerical value assigned for each condition (Appendix 2B), and the assigned values were summed and summary values were computed for each silvery minnow (Appendix 2I). These values were then used to calculate the mean HAI and were compared by sample year, month (quarterly corresponding to season), and site.

A Feeding Index was also calculated using bile fullness and color according to Goede (1993). The Feeding Index is an indicator of time to last feeding and is based on the fullness and color of bile in the gallbladder. Both fullness of the gallbladder and color of the bile are directly related to movement of digested material into the gut (Goede 1993). The gallbladder remains empty while food is being moved through the gut. In the absence of food, bile is stored in the bladder where oxidation of pigments begins to change bile color over time from yellow to dark green. The four categories for measuring bile color and fullness are 0 (bladder empty or partially full), 1 (bladder full, bile is yellow), 2 (bile is light or grass green), and 3 (bile is dark green). These gallbladder

observations were transformed into a Feeding Index according to Goede (1993). A Feeding Index of 100 indicated active feeding among silvery minnows just prior to their collection. A desirable range for the Feeding Index is greater than 67 (Goede 1993).

Data Analyses

Length, weight, opercula shortening, SSI, and HAI data were summarized by sample year, month, and site. Comparisons were also made by sample year, which refers to all observations conducted in Year 1 or Year 2 as described above. Gender was not used to summarize data as not all silvery minnow genders were verified by histopathogical observation and there were numerous silvery minnow of indeterminate gender collected in July. If the summary data met assumptions of normality and equality of variance, a One Way Analysis of Variance (ANOVA) was conducted to determine if significant differences existed. A Student's t-test or Tukey post-hoc tests were used to determine specific differences in the mean. Where data did not meet these assumptions of normality, data were transformed to ranks and a Kruskal-Wallis and median test was applied to test the ranks using Statistica (Statsoft 2011). Other parametric and nonparametric statistical tests were also employed and are so indicated in the text.

Arithmetic means plus or minus one standard error (± 1 SE), or one standard deviation (SD), ANOVA, Student's t-test, and Tukey's post hoc tests were calculated using the software package SPSS Version 13.0 for Windows (SPSS Inc., 2004). Unless otherwise specified, average values are presented plus or minus ± 1SE. Pearson's product-moment correlation coefficients (r) were used to describe the extent to which measured values (or summary data) varied together. Only significant and robust relationships (indicated by correlation coefficients greater than 0.4) were reported unless otherwise specified. Statistical significance refers to a probability (p) of less than or equal to 0.05 unless otherwise stated. Descriptive statistics and figures were generated using Microsoft Excel 2007, SPSS Version 13.0 for Windows, and Statistica (StatSoft Inc., 2010).

RESULTS

A total of 1,070 silvery minnows were observed and processed during sample years (Year 1 and Year 2) (Appendix 2C). Of the silvery minnows observed, females represented 49 percent (n = 522), males 33 percent (n = 352), and 18 percent genders were indeterminate (n = 196) and indeterminate genders were not further evaluated. Overall, 111 silvery minnows (10 percent) contained a Visible Implant Elastomer (VIE) tag used to identify hatchery-reared silvery minnows (U.S. Fish and Wildlife Service 2010). These VIE tagged silvery minnows were noted and included in all fish health assessments and data analyses. A total of 178 (17 percent) of the silvery minnows collected were further used for histology and histopathology (Papoulias et al. 2009).

Silvery Minnow Total Length

Year 1 silvery minnows were significantly greater in mean TL than those collected during Year 2 ($t = 17.19_{(1,063)}$; $p < 0.001$) (Figure 5; Appendix 2D). During Year 1, the April mean TL was significantly smaller than in all other months sampled (ANOVA; $F = 10.124_{(5, 507)}$, Tukey post-hoc, $p < 0.01$) (Figure 5). Mean TL was similar for all other months sampled during Year 1. Site 5 had the smallest mean TL, significantly different from all other sites except Site1 and Site 2 (ANOVA; $F = 12.603_{(5, 505)}$, Tukey post-hoc, $p < 0.006$) (Figure 6). The April mean TL was significantly smaller than in all other months sampled during Year 2 (ANOVA; $F = 10.124_{(3, 507)}$; Tukey post-hoc, $p < 0.01$) (Figure 6). During Year 2, differences among Sites 1, 2, and 3 mean TL were observed as well as differences among Sites 4, 5, and 6 mean TL (ANOVA; $F = 9.188_{(5, 548)}$; Tukey post-hoc. $p < 0.03$) (Figure 6).

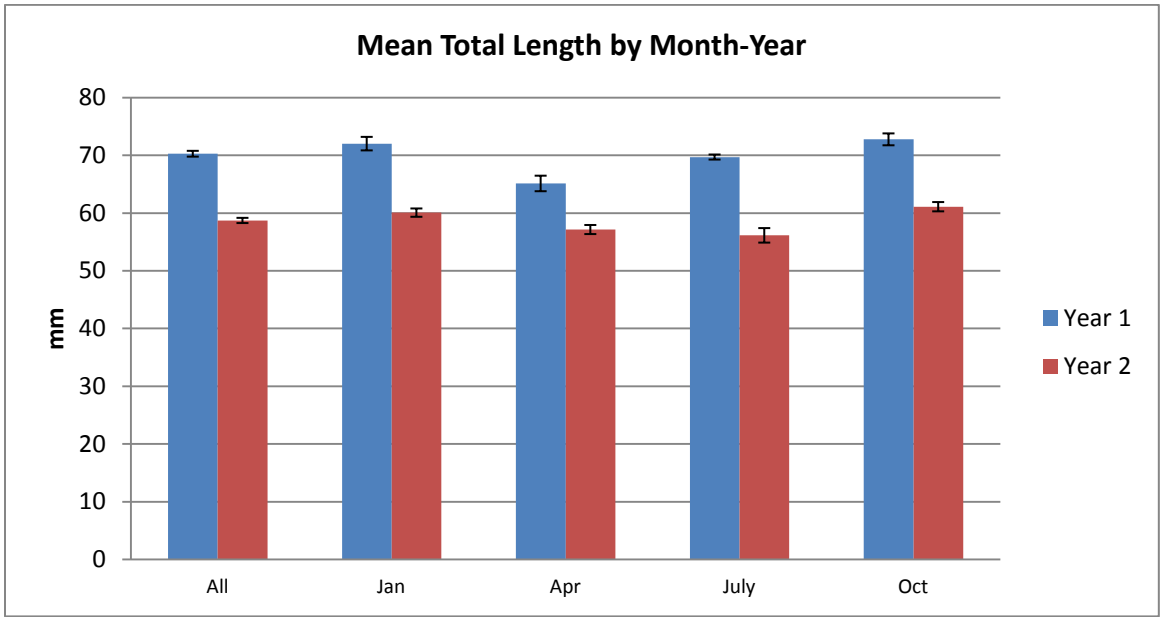

Figure 5. Mean total length of silvery minnows by month and sample year. Error bars represent ± 1 SE.

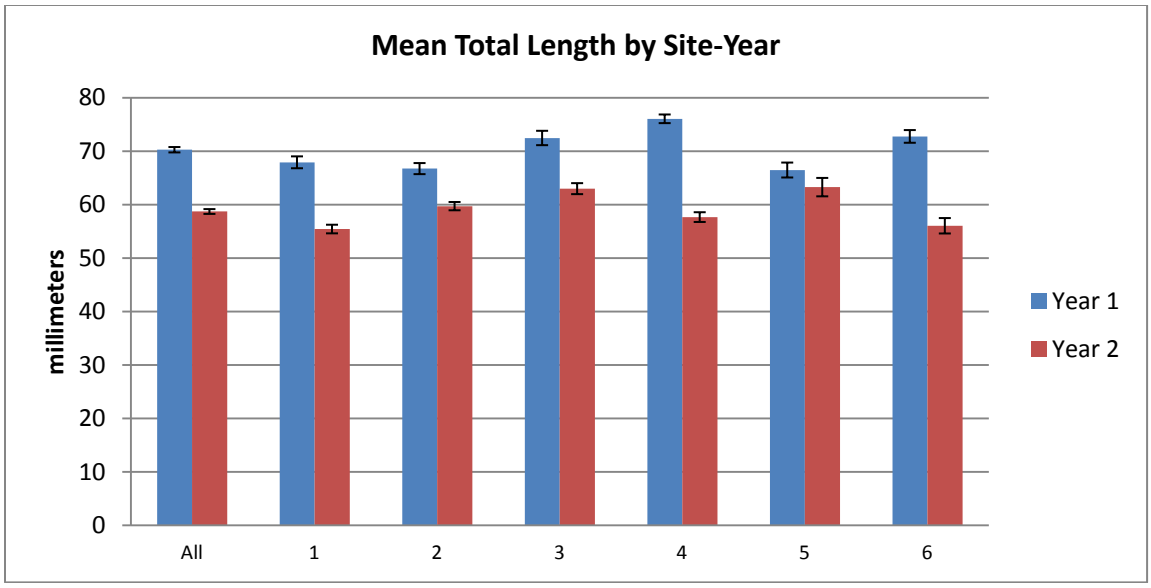

Figure 6. Mean total length of silvery minnows by site and sample year. Site numbers and names are listed in Table 1. Error bars represent ± 1 SE.

Silvery Minnow Weight

Silvery minnows collected ranged in weight from 0.25 to 8.0 g (average 2.8±1.4 g). Silvery minnows collected in Year 1 (3.10±1.5 g) had a significantly greater mean weight ($t = 15.795_{(1067)}$; $p < 0.001$) than found in Year 2 (1.89±1.0 g) (Figure 7; Appendix 2E). In Year 1, the mean weight of silvery minnows collected in October and July differed from one another (ANOVA; $F = 4.426_{(3, 512)}$; Tukey post-hoc, $p = 0.01$). Silvery minnows collected at Site 4 (Rio Grande at Los Lunas) had significantly greater mean weight (3.96±1.3 g) than from all other sites sampled during Year 1 (ANOVA; $F = 14.516_{(5, 510)}$; Tukey post-hoc, $p < 0.05$) (Figure 8). Silvery minnows from all months sampled during Year 2 had similar mean weight (Figure 7). Site 3 mean weight was significantly greater than all other sites except Site 5 during Year 2 (ANOVA; $F = 11.877$ (5, 547); Tukey post-hoc, $p < 0.003$) (Figure 8).

Splenosomatic Index (SSI)

Year 1 mean SSI did not differ significantly from Year 2 mean SSI (Figure 9; Appendix 2F). During Year 1, July mean SSI differed from all other months sampled (ANOVA; $F = 11.668_{(3, 508)}$; Tukey post-hoc, $p < 0.001$) (Figure 9). Year 1 Sites 1 and 2 mean SSI differed from Sites 4 and 5 (ANOVA; $F = 5.548_{(5, 506)}$; Tukey post-hoc), $p < 0.02$) (Figure 10). All other comparisons among sites were similar during Year 1.

During Year 2, April mean SSI was significantly lower than the mean SSI from all other months sampled (ANOVA; $F = 9.478_{(2, 228)}$; Tukey post-hoc, $p < 0.016$) (Figure 9). There were no differences in mean SSI among sites sampled during Year 2 (Figure 10). Although an individual silvery minnow from Site 3 had an SSI of 2.89, the mean SSI for Site 3 during Year 2 did not significantly differ from other sites sampled (Figure 10).

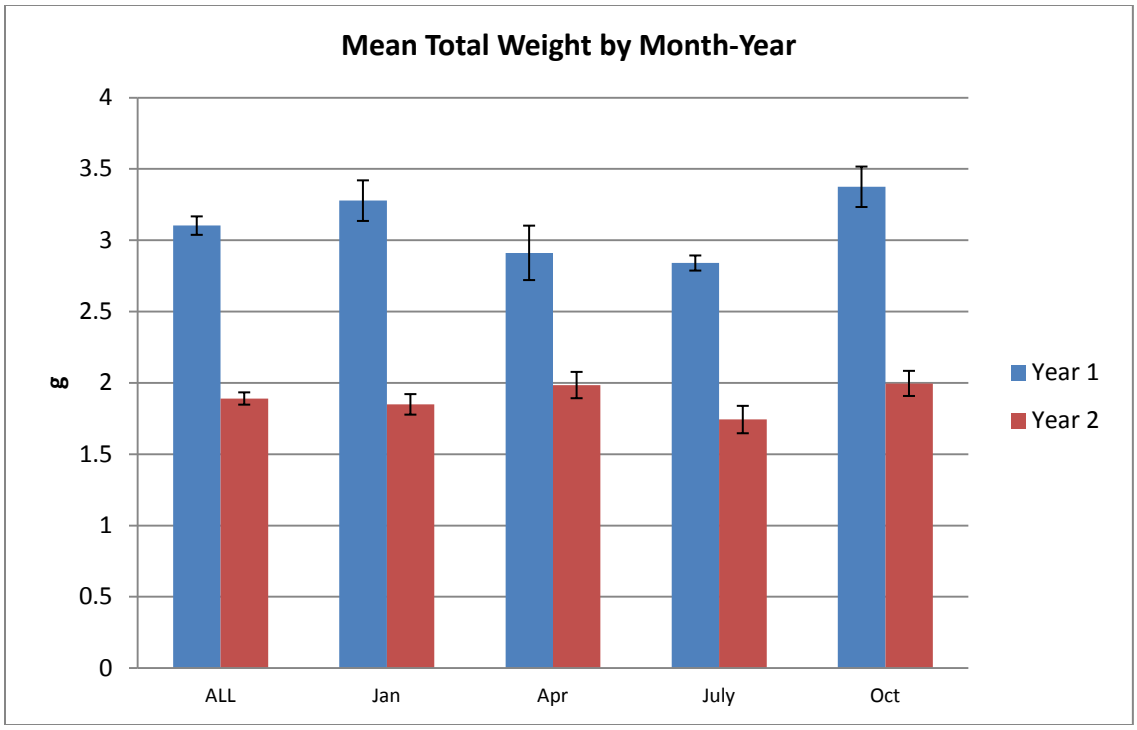

Figure 7. Mean weight of silvery minnows by month and sample year. Error bars represent ± 1 SE.

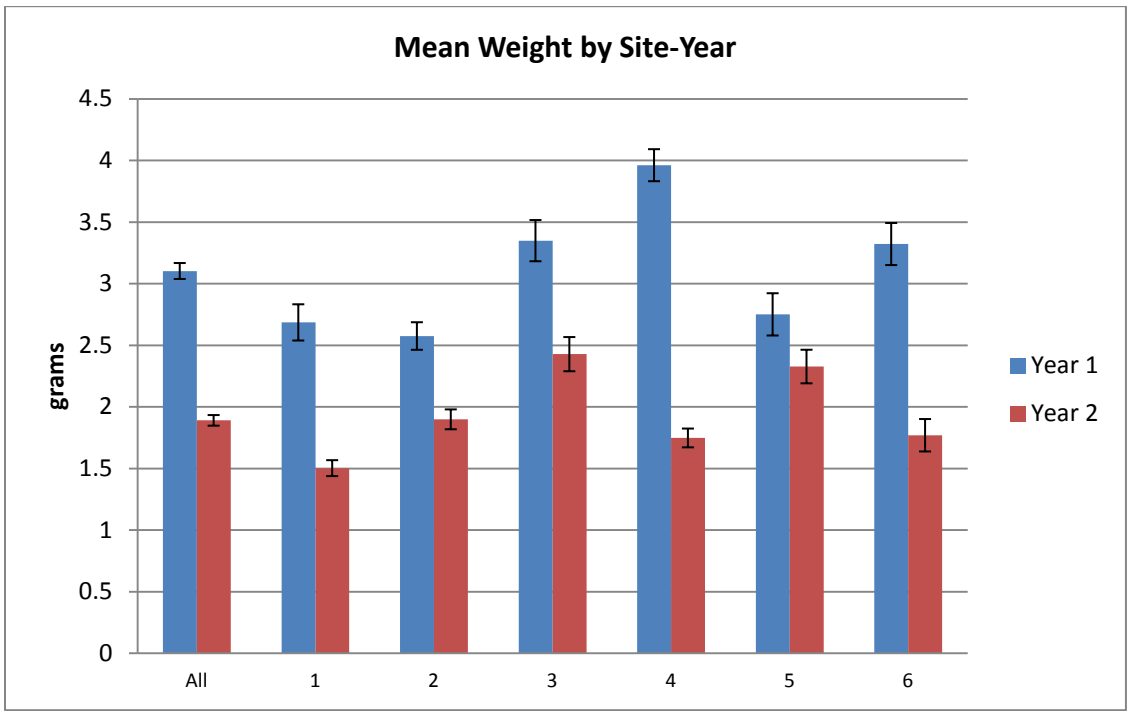

Figure 8. Mean weight of silvery minnows by site and sample year. Site number and names are listed in Table 1. Error bars represent ± 1 SE.

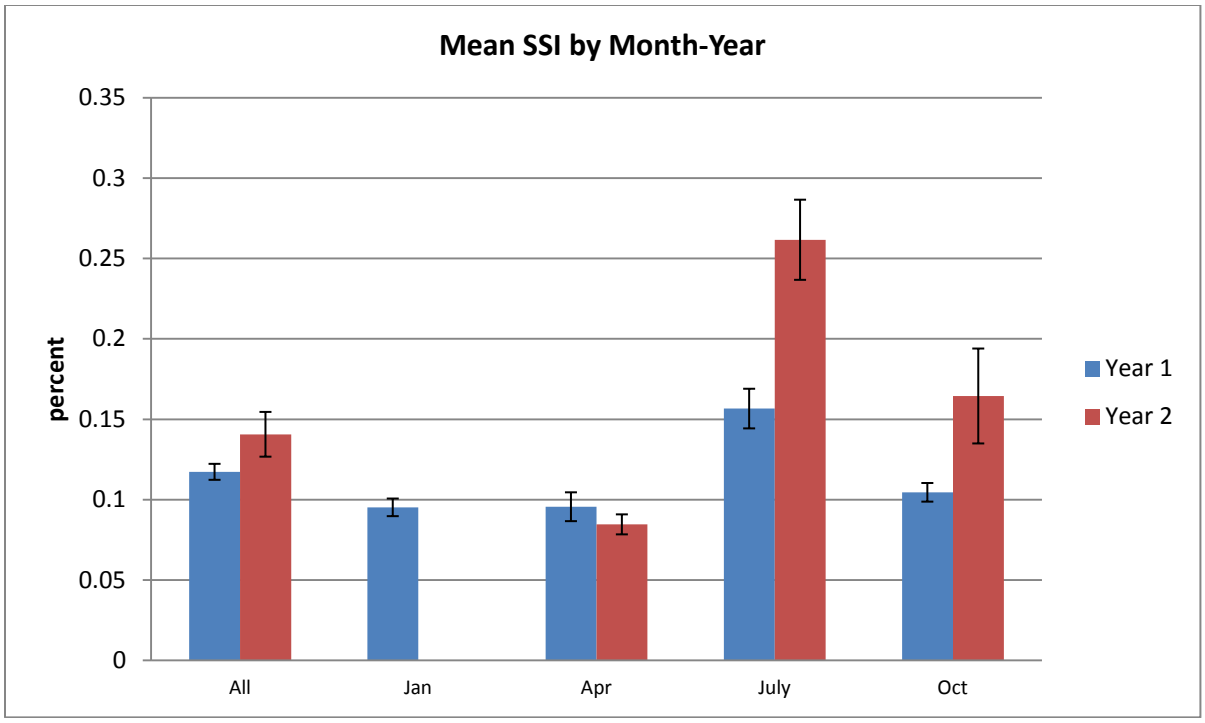

Figure 9. Mean SSI for silvery minnows by month and sample year. Error bars represent ± 1 SE.

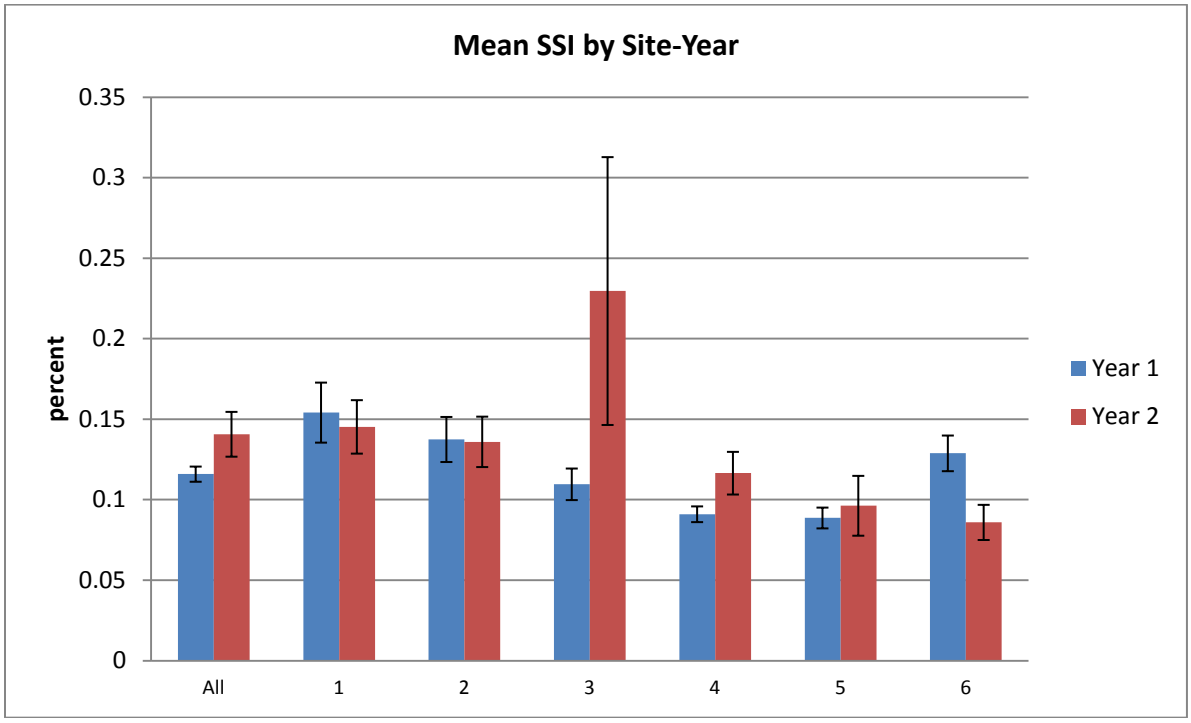

Figure 10. Mean SSI for silvery minnows by site and sample year. Site number and names are listed in Table 1. Error bars represent ± 1 SE.

Health Assessment Index (HAI)

Silvery minnows collected in Year 1 had a significantly lower mean HAI score than from Year 2 ($t = -5.559_{(1068)}$; $p < 0.001$) (Figure 11; Appendix 2G). During Year 1, July HAI scores differed from both April and October mean HAI scores (ANOVA; $F = 6.265_{(3, 512)}$; Tukey post-hoc, $p < 0.005$) (Figure 11). Year 1, Site 1 had significantly lower mean HAI scores than all other sites except Site 2 (ANOVA; $F = 11.061_{(5, 510)}$; Tukey post-hoc, $p < 0.001$) (Figure 12).

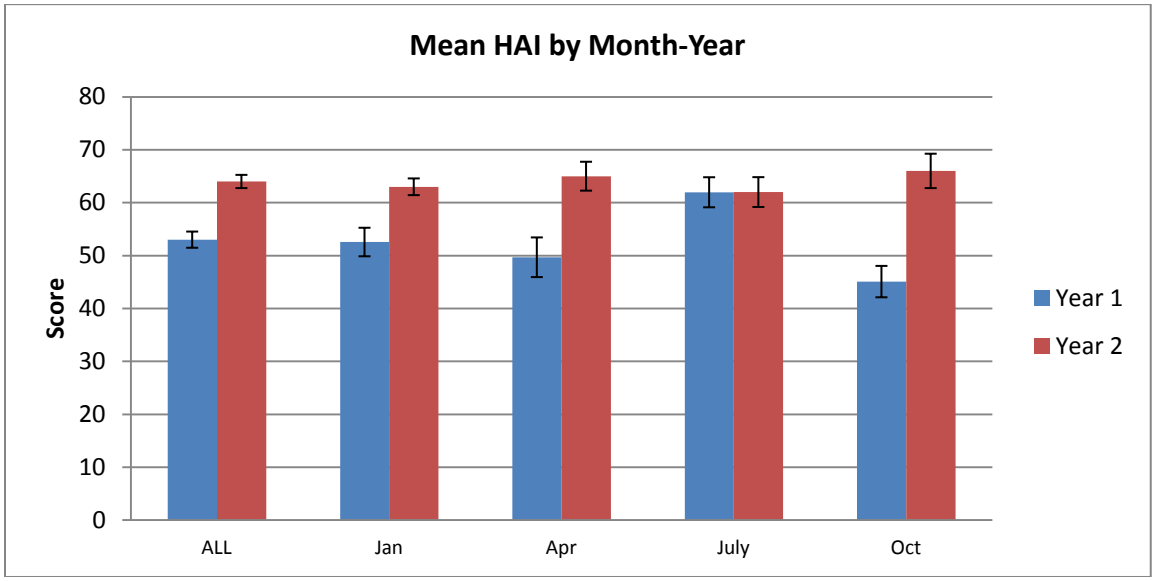

Figure 11. Mean HAI for silvery minnows by month and sample year. Error bars represent ± 1 SE.

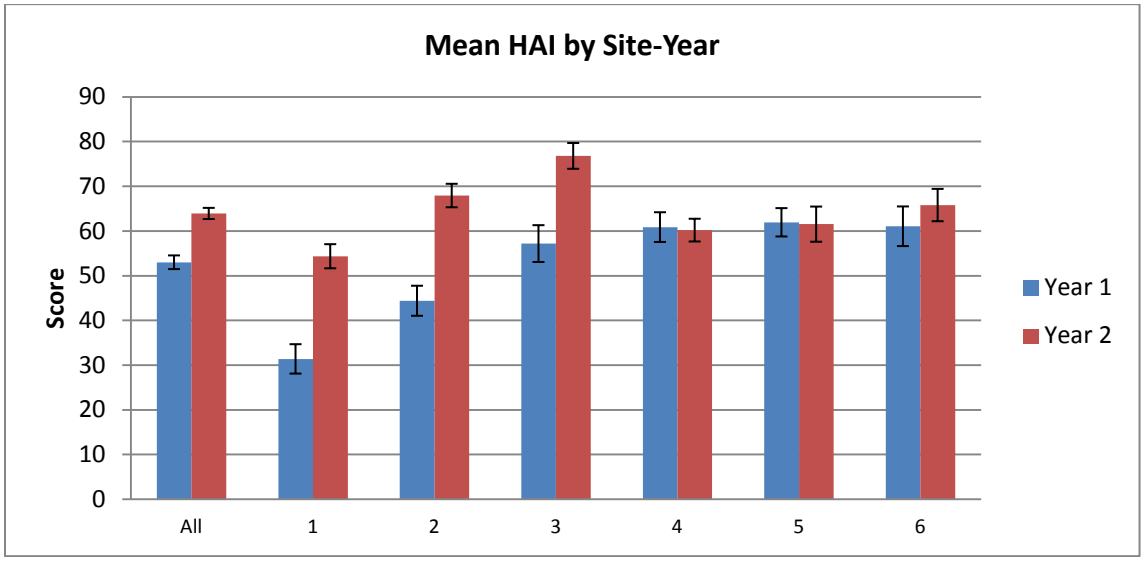

Figure 12. Mean HAI for silvery minnows by site and sample year. Site number and names are listed in Table 1. Error bars represent ± 1 SE.

Silvery minnows collected in Year 2 had similar HAI in all months. There was a significant difference among mean HAI scores from upstream Sites 1, 2, and 3 (ANOVA; $F = 6.767_{(5, 548)}$; Tukey post-hoc, $p < 0.006$) (Figure 12); however, there was no difference among downstream Sites 4, 5, and 6.

Feeding Index

During Year 1, the mean Feeding Index in silvery minnows collected in July was significantly lower than those collected in January or December (Kruskal-Wallis test: $H = 25.51_{(3, 509)}$ $p < .001$) (Figure 13). There were no significant differences in Feeding Index by site in Year 1 (Figure 14). During Year 2, the mean Feeding Index in silvery minnows collected in July was significantly lower than those collected in January or December (Kruskal-Wallis test: $H = 24.93_{(3, 542)}$ $p < .001$) (Figure 13). There were no significant differences in Feeding Index by site in Year 2 (Figure 14). The Year 1 mean Feeding Index was significantly lower than in silvery minnows collected during Year 2 (Kruskal-Wallis test: $H=67.04365_{(1, N= 1051)}$; Chi-Square = 20.89, $p < 0.001$).

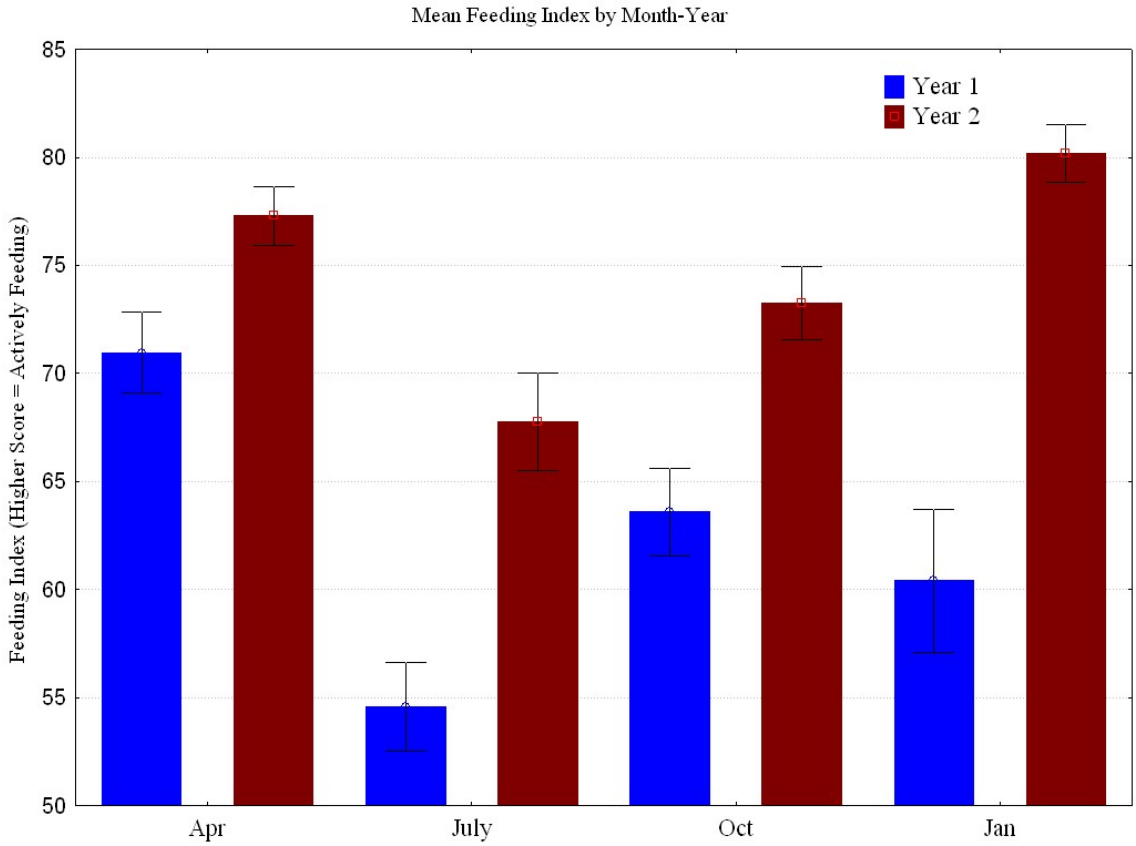

Figure 13. Mean Feeding Index for silvery minnows by month and sample year. Error bars represent ± 1 SE.

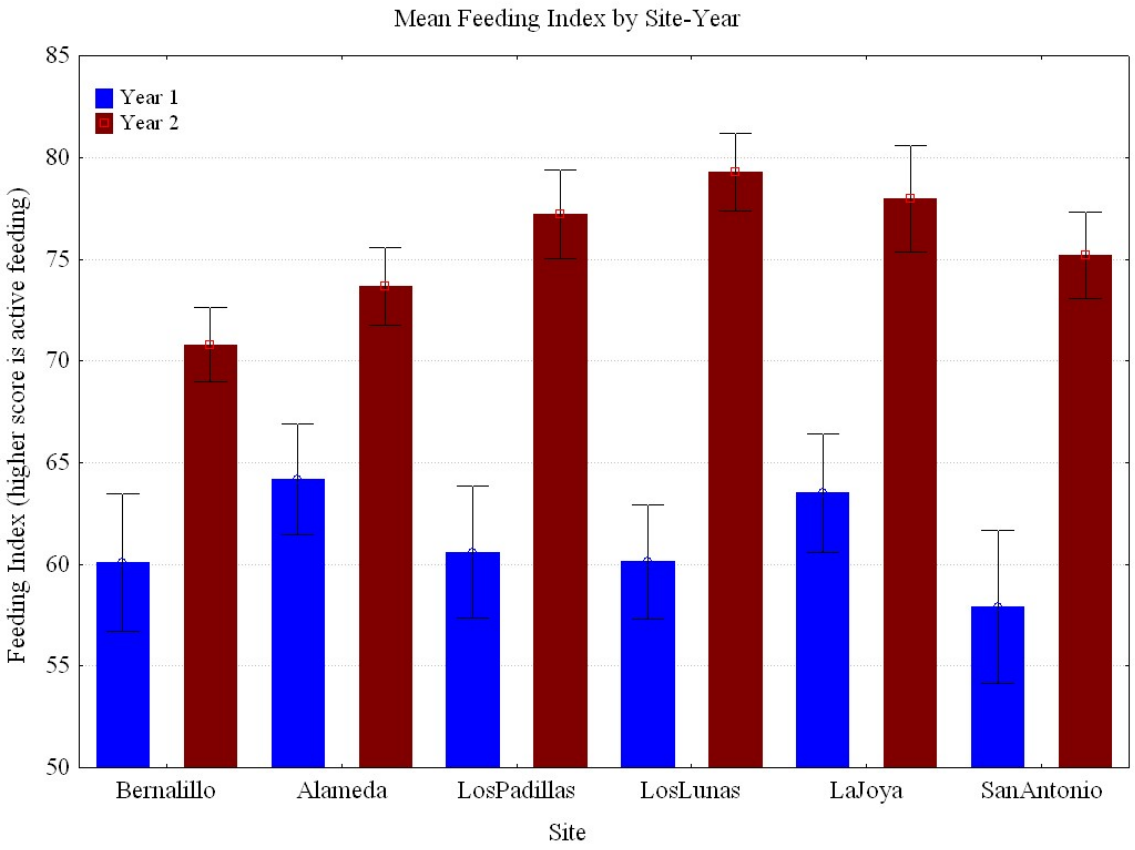

Figure 14. Mean Feeding Index for silvery minnows by site and sample year. Sites are further described in Table 1. Error bars represent ± 1 SE.

Silvery Minnow Opercula

Shortened opercula were the most prevalent gross abnormality observed in both Year 1 and Year 2 silvery minnows sampled (Figure 15; Appendix 2H.). The overall frequency of occurrence was less during Year 1 (50 percent) compared with Year 2 (89 percent). During Year 1, this anomaly was partially bilateral (i.e., 40.9 percent had equally shortened opercula). The unilateral abnormality was observed 3.7 percent just on the right side and 5.8 percent on just the left side. The remaining silvery minnows had varied shortening of both opercula (49.6 percent). During Year 2, this anomaly was largely bilateral (83.2 percent). The unilateral abnormality was observed 2.9 percent on just the right side and 3.1 percent on just the left side, and remaining silvery minnows had varied shortening of both opercula.

In Year 1 the observed frequency of shortened opercula increased during April (68 percent) and July (65 percent) and decreased during January (38 percent) (Figure 15). In Year 2 observations of shortened opercula in silvery minnows were elevated during January (98 percent) (Figure 15), and slightly lower in July (86 percent) and October (79 percent). During Year 1, the highest frequency of opercle shortening was observed in silvery minnows from Site 5 (Figure 16). During Year 2, all six sites had high occurrence (greater than 70 percent) of shortened opercula (Figure 16).

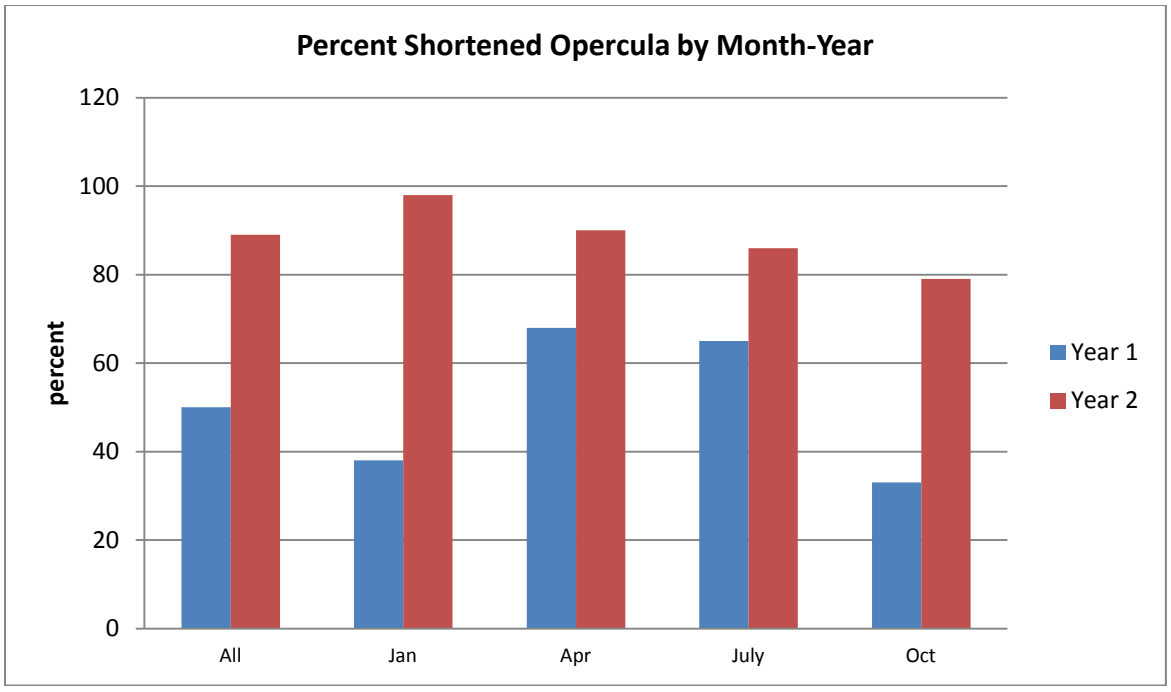

Figure 15. Mean percent of shortened opercula observed in silvery minnows by month and sample year.

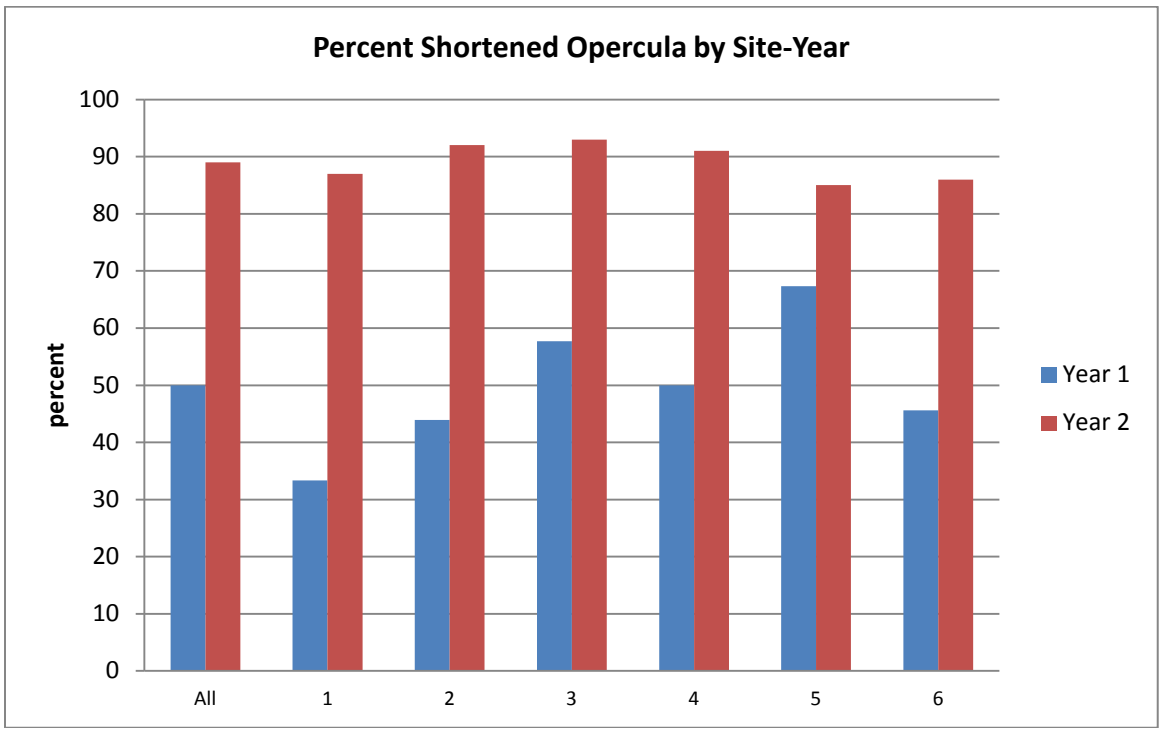

Figure 16. Mean percent shortened opercula observed in silvery minnows by site and sample year. Site number and names are listed in Table 1.

Summary of Silvery Minnow Health Observations

Silvery minnow health observations, measurements, notes, and index scores are summarized in Appendix 2I. We observed a number anomalies including parasites, skin ulcers, fin erosion, tumors, enlarged or reduced organs, organ discoloration, nodules, and other deformities (e.g., Figures 1 and 2). Photographs taken were stored digitally and selected photos were labeled and provided in Appendix 2J (Plates 1-58). In additon to shortened opercula, some of the anomalies seen at a high frequency were clubbing of the gills and liver discoloration. Gill anomalies such as clubbing, may indicate bacterial or parasite exposure or other water quality stressors. Liver discoloration may signify fatty deposits, metabolism or vitamin deficiencies, disease, or exposure to certain contaminants (Schmitt and Dethloff 2000; Hinton at al. 1992; Goodbred et al. 1997).

In this study, the health anomolies seen in silvery minnows at the greatest frequency were shortened opercula (70 percent), liver (52 percent) and gill (50 percent) (Figure 17; Appendix 2H). During Year 1, 50 percent of silvery minnows observed had shortened opercula. InYear 2, that percentage increased to 89 percent. Liver anomalies were high for both years, 45 percent of livers examined during Year 1 had discolored or anomalies. During Year 2, discolored or anomalous livers increased to 59 percent. Gill anomalies were observed in 44 percent examined during Year 1. In Year 2 that percentage increased to 56 percent. Kidney anomalies were observed in 16 percent during Year 1. In Year 2, kidney anomalies increased slightly to 24 percent. External lesions and tumor observations decreased from Year 1 from 25 percent to 13 percent in Year 2. Spleen anomalies appeared to decreased as well, 22 percent in Year 1 to 9 percent in Year 2.

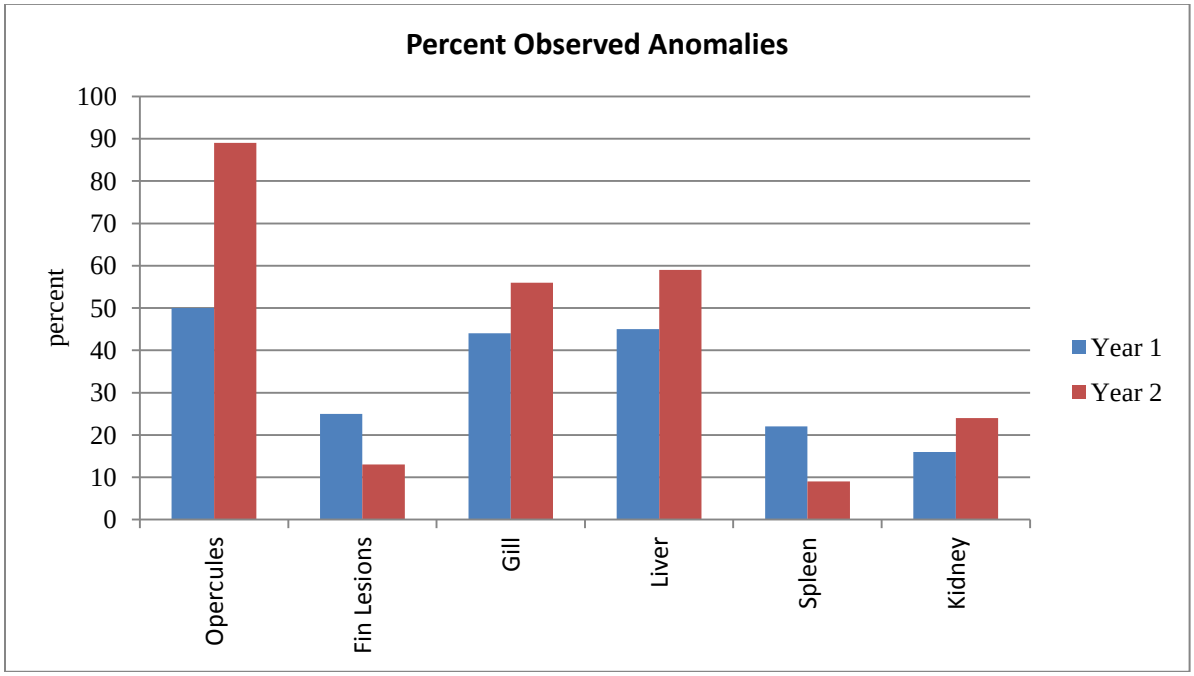

Figure 17. Mean percent of anomalies observed in silvery minnows by type and sample year.

DISCUSSION

Fish may be regarded as representative indicators of environmental health because of their position and function within river ecosystems. Impairments of fish health may indicate contaminants or other stressors within the aquatic ecosystem, some of which could remain undetected by traditional water quality monitoring techniques. In the mid-1990s, the USGS developed and implemented several watershed-based fishery monitoring projects using a standard suite of methods designed to detect changes in the overall condition of large-bodied fish as well as provide information about the status, health and welfare of individual fish and their subpopulations over time (Schmitt et al. 1995; Bartish et al. 1997, Schmitt et al. 1999) including in the Rio Grande. We used and modified these fish health observation methods to accommodate small-bodied species such as silvery minnows. These health observations were implemented as a means to characterize the health of silvery minnows along with other concurrently measured parameters such as water quality in order to maximize the information available about factors contributing to the health condition of silvery minnows in the Rio Grande over time.

Length and Weight

Generally, fish metabolism and growth (as measured by length and weight) increase positively with water temperature (von Bertalanffy 1957). Both mean TL and weight were significantly greater during Year 1. Lusk (2012a) reported that average water temperatures (95 percent confidence intervals) were colder during Year 2 (11.9-12.1°Celsius (C)) than Year 1 (13.9-14.1°C). For both years, Site 1 and Site 6 had the lowest mean TL and weight and the average water temperatures at Site 1 (12.1-12.5°C) and Site 6 (11.6-12.1°C) were generally colder than measured at Site 2 (14.0-14.3°C), Site 3 (12.7-13.0°C), Site 4 (13.5-13.8°C), or Site 5 (13.0-13.2°C) (Lusk 2012a). Also, silvery minnows were feeding more actively in Year 2, (based on their mean Feeding Index, below) yet had lower mesenteric fat reserves in Year 2, and therefore, we suspect water temperature may have had a predominant role in size of silvery minnows measured.

Indices of Fish Health

Indices of fish health have been used extensively in population assessments as indicators of well-being of individual organisms (Adams 1990; Goede and Barton 1990). Fish health assessments were relatively simple and inexpensive to perform. Fish health indices can reflect the status of organ systems, which may change in size due to environmental factors more rapidly than whole body weights change in size. The relative weights of organs such as liver and gonads relative to total weight may signify overall health or reproductive status of a fish (Busacker et al. 1990), but for this study, only SSI, HAI, Feeding Index were evaluated as general indicators of fish health as we were unable to evaluate a hepatosomatic or gonadosomatic index for these cyprinids due to the dispersed nature of their liver and gonads. Additionally, a high degree of size variation was seen in silvery minnow gonads during different life stages observed over each year.

Splenosomatic Index (SSI)

The condition and morphology of the spleen can be useful as a diagnostic tool because it is associated with the storage of red blood cells and may support immune system response in fish species (Anderson 1990; Franklin et al. 1993; Schmitt and Dethloff 2000). However, spleen sizes vary among fish species, and even within the same species. Age, gender and gonad development are also factors that may affect spleen weight (Schmitt and Dethoff 2000). Acute or nonspecific stressors such as temperature changes, hypoxia, extreme exercise, and exposure to chemical contaminants have also affected spleen weight (Franklin et al. 1993; Schmitt and Dethloff 2000). An enlarged spleen may also suggest disease or an immune system disorder due to increased hypertrophy or proliferation of leukocytes and other blood cell types (Anderson 1990; Goede and Barton 1990). The SSI has been incorporated into monitoring protocols evaluating the Mississippi River (Schmitt 2002), Colorado River (Hinck et al. 2006) as well as the Rio Grande Basin (Schmitt et al. 2004, 2005).

In this study, spleen weight was measured and recorded to the nearest 0.001 g. In some instances, the spleen was too small to weigh accurately and thus no weight was recorded. When we compared the SSI data, Year 1 and Year 2 SSI were not significantly different. SSI in silvery minnows were also similar to those in large bodied fish collected from the Rio Grande (Schmitt et al. 2004). In both years the mean SSI was less than 0.2 percent, with the exception of one silvery minnow collected during July 2008 from Site 3 that had a SSI of nearly three percent. However, on average, the SSI did not change over time, although the number of spleen anomalies did appear to decrease between sample years.

Health Assessment Index (HAI)

The greater the mean HAI, the greater the number of lesions or other anomalies observed. Studies have indicated that fish in severely polluted areas exhibit a higher frequency of lesions than those in similar, but less polluted areas (Schmitt and Dethloff 2000). Mean HAI scores of silvery minnows were significantly greater in July compared to those sampled in other months in Year 1. Mean HAI scores were significantly lower in Year 1 than in Year 2. Mean HAI scores at Site 1 were relatively good (less than or equal to 30) during Year 1, but mean HAI scores at Site 1, Site 2, and Site 3 increased during Year 2. Mean HAI scores tended to increase downstream at and below Site 3, and remained elevated downstream to Site 6; suggesting that the cumulative condition of the silvery minnows deteriorated from upstream to downstream.

Although exposure to environmental contaminants alone can induce anomalies detected by the HAI score, it must be recognized that more often the development of gross lesions may be influenced by diet, certain water quality parameters, seasons and weather events, handling stress, or capture methods (Schmitt and Dethloff 2000; Papoulias et al. 2009). The HAI scores in silvery minnows tended to reflect external anomalies as well as their gill and liver conditions, rather than relate to average concentrations of pollutants reported in water, sediment, or fish tissues collected contemporaneously by the New Mexico Environment Department (NMED 2009) or as reported by Lusk (2012b). Certain

water quality parameters such as water temperature, pH, or specific conductivity may play a role in the development of skeletal (see opercula discussion below) or other anomalies and their averages were significantly greater in Year 2 than in Year 1 (Lusk 2012a). Additionally, suspended sediment concentrations measured at nearby USGS gage stations were higher in Year 1 (2,888±7813 mg/L) than in Year 2 (1,104±1436) (Lusk 2011). Increases in some of these water quality parameters (i.e., temperature, specific conductivity) as well as pathogen burdens tended also to be higher in July. Since Feeding Index improved in Year 2 (see below), as did measures of average gross primary productivity (Lusk 2012a), the increased mean HAI scores did not seem to be related to their feeding activity or other measures of productivity. It was difficult to completely assess the observed variations in the HAI to these water quality stressors, and therefore, the HAI may also be related to stressors that we did not measure adequately.

Feeding Index

Silvery minnows were more actively feeding at all sites in Year 2 than in Year 1. Lusk (2012a) reported that average gross primary productivity was significantly higher in Year 2 than in Year 1. This suggested that Feeding Index in silvery minnows could be related to average measures of gross primary productivity . However, average gross primary productivity was highest in July and lowest in April (Lusk 2012a), whereas the Feeding Index was lowest in July and highest in January and April. Therefore, Feeding Index and measures of average gross primary productivity may not be closely related, although it is possible that reduction of feeding may have occurred during July, or possibly, that the relative nutrition content of silvery minnow diets may also change during summer. Suspended sediment concentrations measured at nearby USGS gage stations were generally higher in Year 1 (2,888±7813 mg/L) than in Year 2 (1,104±1436) and may also have played a role in silvery minnow feeding or food availability (Lusk 2011).

Shortened Opercula or Fish Opercula Deformity Syndrome (FODS)

Skeletal deformities have been reported in other fish species and can affect the head, eyes, opercula, as well as vertebra (Al-Harbi 2001). Many studies observe that shortened opercula occurs during fish development as a non inherited congenital defect induced during the embryonic or larval stage, (Tave et al. 1982; Tave and Handwerker 1994; Koumoundouros et al. 1997; Tave et al. 2011), however, Lindesjöö et al. (1994) found shortened opercula in fish by year of exposure based on growth rings that coincided with later-in-life exposure. Skeletal malformations in fish can arise from a number of causes including: nutrient deficiency, particularly vitamin C or amino acid deficiency (Lim and Lowell 1978; Sato et al. 1982; Backiel et al. 1984; Chavez De Martinez 1990; Grady et al. 1992b; Koumoundouros et al. 1997; Dabrowski et al. 1988; Madsen and Dalsgaard 1999; Lall and Lewis-McCrea 2007), environmental contamination including metals (e.g., selenium, zinc, copper, cadmium, mercury and lead) and polychlorinated biphenyl (PCB) compounds (Grady et al. 1992b; Olsson et al. 1999; Antunes et al. 2002; Lemly 2002; Jawad 2004; Koca et al. 2005;), temperature conditions during development (Georgakopoulou et al. 2010), turbulence and elevated gases (Backiel et al. 1984; Al-Harbi 2001; Beraldo et al. 2003), parasites or infectious diseases (Lom et al., 1991),

genetic defects (Piron 1978; Al-Harbi 2001; Verhaegen et al. 2007; Tave et al. 1983; Koumoundouros et al. 1997; Beraldo et al. 2003), and mechano-transduction (the loss of bone density due to reduced activity) (Danos and Staab 2010).

Skeletal anomalies such as shortened opercula can affect fish feeding, respiration, swimming, normal morphology, growth and productivity (Sadler 1990; Lom et al. 1991; Koumoundouros et al. 1997; Al-Harbi, 2001; Lemly 2002; Verhaegen et al. 2007; Eissa et al. 2009). Opercula having normal structure and function are fundamental to fish health because impairment can reduce growth, lower resistance and defense against pathogens, and reduce the mechanical efficiency of feeding and respiration (Beraldo et al. 2003).

Shortened opercula was the anomaly seen at the highest frequency in silvery minnows we collected. The opercula were observed with shortening on one or both opercula. Shortened opercula has been reported in three other fish species collected from the Rio Grande including river carpsucker (*Carpoides carpio*), fathead minnow (*Pimephales promelas*), and red shiner (*Cyprinella lutrensis*) (Sykes 2003, Abeyta and Lusk 2004a). Silvery minnows in hatcheries have also been identified with 40 to 90 percent shortened opercula (Buhl 2011). Additionally, fish collected from the San Juan River Basin have been identified with shortened opercula. As shortened opercula have been observed in several different fish species collected from two large river basins, as well as in hatchery fish, we saw it as a widespread phenomena and termed it “Fish Opercula Deformity Syndrome” (or FODS). After these observations, we sought to evaluate the historical incidence of FODS in silvery minnows collected over time to gain more information.

Separate from this Rio Grande Silvery Minnow Health Study (and hence discussion of methods and results here), we evaluated the incidence of FODS in silvery minnows that have been collected by others at different locations over time. We worked with the University of New Mexico, Museum of Southwestern Biology (Museum), Fishes Division Collection Manager to identify those "lots" (that is, unique catalog numbers) of archived silvery minnows most similar to our own collections. That is, we identified those lots that had over 29 silvery minnows collected and with collection season and sizes that were within the range we collected (i.e., greater than 41 to 92 mm TL). Ultimately, we identified 25 "lots" (catalog collection numbers: 1119, 1120, 1125, 1130, 1151, 1155, 1162, 1171, 3961, 4338, 4384, 5730, 5934, 11589, 13472, 20396, 22671, 30032, 30246, 39103, 45271, 43314, 44627, 48229, and 49969) for FODS observations. Working with volunteers from the University of New Mexico and American Southwest Ichthyological Researchers, L.L.C., we removed, weighed, and measured total length, and observed both opercula from 30 randomly selected silvery minnows from 25 different years (Figure 18). We observed FODS in silvery minnows as early as 1938 from the archival sample lots we selected (Appendix 2K; Figure 18).

Below, we discuss several of these causes and evaluate whether they may or may not provide a potential explanation for the incidence of FODS in silvery minnows.

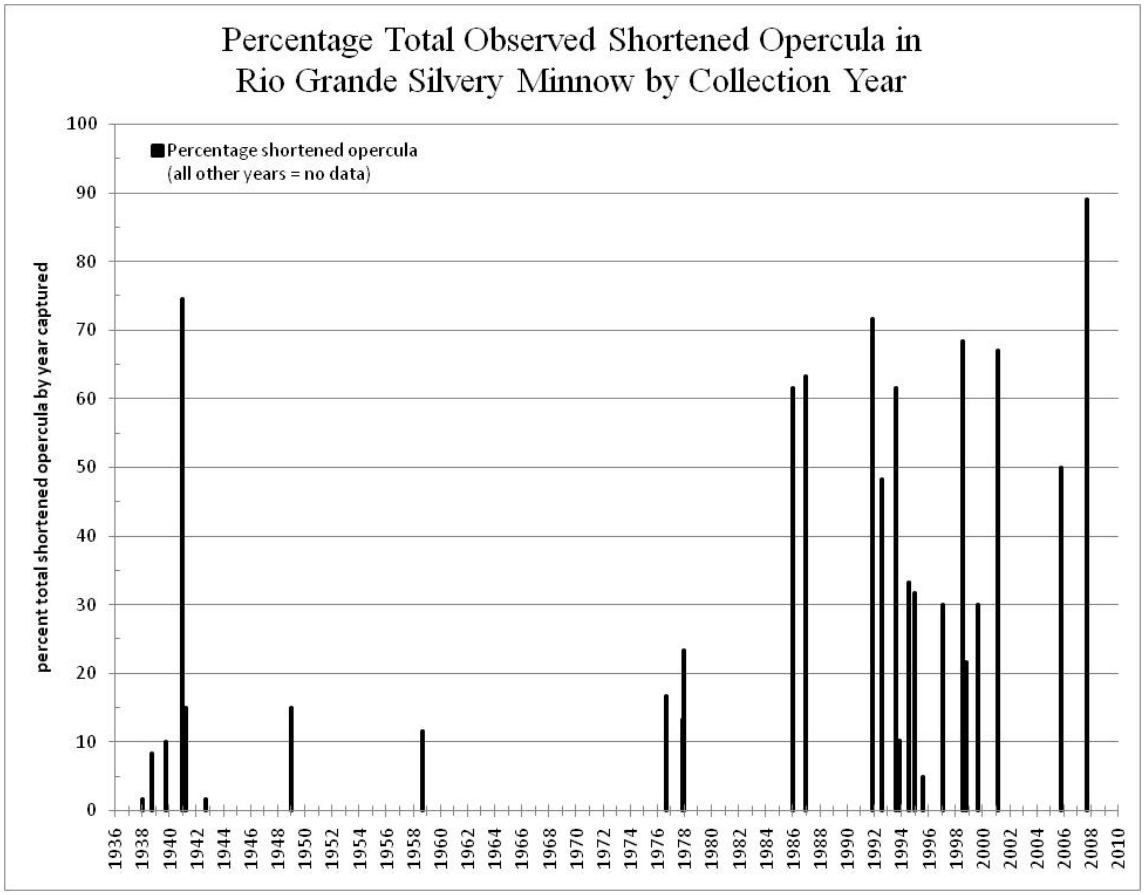

Figure 18. Percent shortened opercula in silvery minnows archived at the University of New Mexico, Museum of Southwestern Biology and in this study by year.

Turbulence and Suspended Sediment: During our study, suspended sediment concentrations averaged 1,936 mg/L at nearby USGS gage station and may provide abrasion to fish tissues including opercula. However, Papoulias et al. (2009) reported that opercula cleared for staining of bone and cartilage did not show signs of abrasion, but rather a reduced bone density as compared with opercula from silvery minnows reared in hatcheries. FODS also occurs in silvery minnows that were reared in hatchery water without suspended sediment. Silvery minnows in hatcheries are also raised in a carefully controlled environment and are protected from normal stress, trauma, and contusions that they would likely encounter in the wild environment. Therefore, we concluded that suspended sediment was not likely a direct factor in the incidence of FODS as it occurred in hatchery fish reared in water without suspended sediment and observations of shortened opercula did not appear to be the result of abrasion.

Genetic defects: Piron (1978) reported that tropical aquarium fish subjected to intensive inbreeding gave rise to a high incidence of spontaneous skeletal deformities which were related to a genetic defect rather than an environmental stimulus. Breeding and augmentation programs address the issue of inbreeding in silvery minnows, so a hereditary defect this does not appear to be an explanatory factor for the incidence of

FODS. Additionally, it is unlikely that the same pattern of genetic instability would occur in five different species of wild fish in two separate river basins.

Environmental Contamination: Lindesjöö et al. (1994) suggested that when fish detoxify pollutants they use their available vitamin C reserves for the detoxification process and thereby reduce the vitamin C available for collagen synthesis resulting in bone density losses and increased deformity rates. Olsson et al. (1999) reported opercula deformities associated with PCB exposure (particularly with PCB Congener 190) that resulted in larvae with craniofacial malformations, particularly opercula shortening that left the gill arches exposed, similar to our observation of FODS. However, their fish were exposed to PCB concentrations that were approximately 360 micrograms per kilogram (µg/kg), on a lipid basis. Lusk (2012b) reported that the maximum PCB concentrations in silvery minnows were less than 36 µg/kg, on a lipid basis. Additionally, PCB concentrations varied with collection location but the incidence of FODS in silvery minnows were generally consistent between sites within collection years (Figure 16). As PCB use was likely low during 1938, it is unlikely that PCB exposure is responsible for the incidence of FODS in the silvery minnows collected during that time. Additionally, hatchery-reared silvery minnows also have been exposed to feeds that contain trace amounts of PCBs, (Maule et al. 2007), we assumed that feed quality has been improved (Tacon and Metian 2008) over time and varied independent of FODS observations in silvery minnows reared in hatcheries.

However, due to their structural similarity with PCBs and their affinity for the same cellular receptors (Luthe et al. 2007), it is possible that some brominated diphenyl ether compounds (BDEs; flame retardant chemicals) may be found with mechanisms of toxicity comparable to PCBs. Lusk (2012b) reported BDE concentrations as high as 50 µg/kg in silvery minnows. Results from the few available laboratory studies indicate that BDEs disrupt thyroid hormones and may have endocrine-disrupting effects on fish (de Wit et al. 2006; Darnerud 2008; Talsness 2008). Thyroid hormones are critical to a developing fish and when they rise transformation begins in larvae and when they drop developmental changes cease. Tomy et al. (2004) reported that fish fed a mixture of BDEs have significantly reduced thyroid hormone concentrations compared with controls not fed BDEs. PCBs, BDEs and other organic compounds have been detected in fishes collected from Rio Grande (NMED 2009) and San Juan River Basins (Hinck et al. 2006), and including in silvery minnows (Lusk 2012b). Therefore, while unlikely, we cannot rule out environmental contamination as a potential cause of FODS in silvery minnows.

Nutrition: Ascorbic acid, or vitamin C, is a water soluble cofactor in many biological processes including collagen synthesis and other cellular and immune functions (Lall and Lewis-McRea 2007). Dietary vitamin C is required for most fish as they are unable to synthesize it to meet their requirements (Halver 2002). Skeletal malformations are common in vitamin C deficient fish and are caused by impaired biosynthesis of collagen (Halver 2002). As fish opercula are primarily made of protein, collagen, and calcium compounds, it is possible that vitamin C or other nutrient deficiency is a factor in the incidence of FODS. Nutritional deficiency could explain the incidence of FODS in silvery minnows (or other native fish species) if the habitat conditions for foods rich in

vitamin C were not readily available for developing fish larvae. Silvery minnows in hatcheries are supplemented with vitamin C (Caldwell 2004), and the incidence of FODS, while elevated (often greater than 50 percent), was not as severe as found in wild silvery minnows (Sykes 2003). Similar to Sykes (2003), we found inconsistent relationships between percent mesenteric fat ($r = -0.43$, $p = 0.004$) or Feeding index ($r = -0.45$, $p = 0.002$) and average percent of FODS in silvery minnows. However, nutritional deficiency remains a potential cause of FODS in silvery minnows. There are number of dietary items, such as diatoms, other plant and algal species, which can contain varying amounts of vitamin C (Brown and Jeffrey 1995), and that may be favored or unavailable in nursery habitats or diets during larval silvery minnow development and growth.

Water Temperature: Georgakopoulou et al. (2010) described and elevated incidence (45-100 percent) of skeletal deformities including FODS in hatchery marine fish due to water temperatures during fish development. They suggested that colder water temperatures had a significant effect on skeletal deformities, especially FODS, and the mechanism was thermally induced alteration of the mechanisms of bone development. We then reviewed available water temperature data and observations of FODS in silvery minnow collected from this study and in historical silvery minnow collections.

In this study, we found the average percent frequency of shortened opercula was negatively correlated with average temperature ($r = -0.42$, $p = 0.007$), suggesting that cold temperatures may play a role in the incidence of FODS. Lusk (2012a) reported that the 95 percent confidence intervals for average water temperatures were colder during Year 2 (11.9-12.1°C) than Year 1 (13.9-14.1°C), and the overall incidence of shortened opercula was 89 and 50 percent, respectively. (While the average percent shortened opercula was also positively correlated with average dissolved oxygen content ($r = 0.50$, $p = 0.001$), we ascribed that correlation to the temperature-dependant solubility of oxygen in water as oxygen saturation was not significantly correlated with incidence of FODS).

We also evaluated the historical incidence of FODS in silvery minnows, with May and June monthly water temperatures (i.e., during larval silvery minnow development), and monthly discharges reported at the Rio Grande at Cochiti, New Mexico (USGS Gage 08314500), and after 1970, below Cochiti Dam, New Mexico (USGS Gage 08317400). We found significant, but not robust correlations, with May ($r = -0.10$) and June water temperatures ($r = 0.25$), as well as a significant correlation ($r = -0.44$) with the mean monthly June discharge. It is likely that monthly water temperature and discharge measurements at USGS gages were inadequate to characterize the quality of nursery habitats for silvery minnows and relate to the observation of FODs in historical silvery minnows.

Also, water temperatures have been found vary by location within the MRG habitat continuum. For example, Abeyta and Lusk (2004a) reported that water temperatures range from 0 to 5.8°C for 37 transects and averaged 1.3±1.3°C across the river widths. Similarly, SWCA Environmental Consultants (2010) described water temperatures in floodplain habitats ranging from 6 to 13°C warmer to 10°C colder than main channel temperatures measured in May and June. Additionally, silvery minnows hatched and

reared at the Dexter National Fish Hatchery and Technology Center have a high incidence but low severity of FODS and their water temperatures range from 22-23°C during early life stages and range from 20-30°C during juvenile development and growth (Sykes 2003; M. Ulibarri, USFWS, written communication, August 2010).

We do not know the thermal optima for proper skeletal development of silvery minnows; however, water temperatures that are either too cold or too warm during fish development may have the potential to cause of FODS in silvery minnows. Dettinger (2005) reported that trends toward earlier snowmelt peak flows in the Rio Grande may be related to observed changes in our climate and these trends may have concomitant changes in water temperatures that may occur during fish development. Additionally, altered water temperatures could also affect the relative availability of different algal species (e.g., Wang and Evans 1969) during larval silvery minnow development. Therefore, while there was some evidence that suggested water temperatures may play a role in the incidence of FODs in silvery minnows, additional research is warranted on this factor.

Mechano-transduction: The vertebrate skeleton responds to mechanical forces and proper mechanical stimulation is required for the maintenance of healthy bones, bone repair, bone density and bone development (Turner et al. 2009; Danos and Staab 2010). The proper formation, density, growth and maintenance of bones depends on the mechanical loads generated by gravity and muscles (Danos and Staab 2010). Mechanical loading by muscle forces affects larval and embryonic bone development when fish are beginning to interact with their environment (Danos and Staab 2010). Annual and peak flows in the Rio Grande Basin has been significantly reduced from historical hydrographs (Julien et al. 2005). However, reduced peak flows due to construction of Cochiti Dam would not likely have affected the incidence of FODS observed in silvery minnows collected before 1978 (Figure 18), although the general frequency of FODS appears to increase thereafter. Additionally, hatchery-reared fish are not commonly subjected to high flood flows during their development and therefore, mechano-transduction may help explain the severity of FODS in silvery minnows reared in hatcheries. As described above, there was a significant negative correlation between the incidence of FODs in historical silvery minnows and discharge measured at USGS gages. It remains unclear whether reduced peak flows or some other discharge-related mechanical forces are involved in the incidence of FODS in silvery minnows.

The incidence of FODS in native fishes of the Rio Grande and in the San Juan River is providing us a signal relaying a complex message in a simplified and useful manner to identify potential environmental stressors that have not been adequately characterized. From our review, it appears that 1) changes in water temperature during fish development, 2) nutritional conditions of the diets of fish early life stages, and 3) changes in discharge-related mechanical forces appear to be the most likely factors affecting the development of FODS in silvery minnows. Gaining a better understanding of their skeletal development in relation to these factors would be important for potentially identifying the causes and management actions needed to reduce the occurrence and effects of FODs in silvery minnows as well as other native fish species.

SUMMARY AND RECOMMENDATIONS

Overall, the anomalies observed at the greatest frequency in silvery minnows included shortened opercula, liver anomalies, and gill anomalies. The level of these anomalies and results on other silvery minnows collected and evaluated contemporaneously (Papoulias et al., 2009; Woodland 2012) suggested that these fish were experiencing chronic stress. Spatially, silvery minnows collected from the upper sites were often healthier than silvery minnows collected from the lower sites, as indicated by the fish health indices and other indicators that tended to increase from upstream to downstream. Particularly, the incidence these anomalies increased during the second year of this study. During Year 2 of this study, water quality conditions were similar except for several pesticides (NMED 2009), water temperature, specific conductivity, and suspended sediment measured at nearby USGS gages (Lusk 2011).

Where appropriate, fish health assessments are recommended for monitoring of silvery minnows over time as it helps quantify their overall condition in relation to various habitat and water quality conditions. We also recommend the expanded use pathogen assessments and histopathology integrated into fish and water quality monitoring programs as they will yield a better understanding of pathogen and tissue trends as they relate to water quality changes in the Rio Grande over time. We also recommend that research be initiated in determining the cause(s) and quantifying the effects of shortened opercula on feeding, swimming, respiration, and growth of Rio Grande silvery minnow.

Appendix 2B. Fish health assessment variables and assigned values. [Field designations as described in Adams et al. 1992; adapted from Schmitt and Dethloff 2000, and described below]

Variable	Variable condition	Field Designation	Value Assigned
Eyes	Normal: no aberration	N	0
	Opaque (one or both)	O	30
	Exopthalmic (one or both)	E	30
	Emboli (one or both)	E	30
	Hemorrhaging (one or both)	H	30
	Missing (one or both)	M	30
	Other: aberration not fitting any above	OT	30
Body Surface (Skin)	Normal: no aberration	N	0
	Mild skin aberrations		10
	Moderate skin aberrations		20
	Severe skin aberrations (tumors, lesions, parasites)	T, L, P	30
Gills	Normal: no aberrations	N	0
	Frayed: ragged appearance (one or both)	F	30
	Clubbed: swelling of tips (one or both)	C	30
	Marginate: light discolored margins (one or both)	M	30
	Pale, very light color (one or both)	P	30
	Parasites (one or both)	P	30
	Other: aberration not fitting any above	OT	30
Fins	No active erosion	N	0
	Mild active erosion	M	10
	Moderate active erosion, some hemorrhage	M, H	20
	Severe active erosion with hemorrhage	S, H	30
Liver	Normal: solid red or light red color	NORMAL	0
	Tan: fatty or coffee w/ cream color	TAN	30
	Nodules or cysts	NOD	30
	Focal discoloration	FOC DIS	30
	General discoloration	GEN DIS	30
Spleen	Normal: Black, dark red to red	RED	0
	Granular: rough appearance	GRAN	0
	Nodular, containing fistulas or nodules	NOD	30
	Enlarged	ENLG	30
	Other: aberration not fitting any above	OT	30
Kidney	Normal: firm, dark, flat	N	0
	Swollen: enlarged or swollen	S	30
	Mottled: gray discoloration	M	30
	Granular in appearance and texture	G	30
	Urolithiasis or nephrocalcinosis: white mineral deposits	U	30
	Other: aberration not fitting any above	OT	30

Appendix 2H**.** Percent abnormalities observed in Rio Grande silvery minnows during Year 1 (2006-2007) and Year 2 (2007-2008) of the Rio Grande Silvery Minnow Health Study.

Anomalies	**Year 1 Percent (n = 516)**	**Year 2 Percent (n = 554)**
Shortened Opercula	50 (n = 260)	89 (n = 494)
External Lesions/Tumors[1]	25 (n = 127)	13 (n = 71)
Gill abnormalities	44 (n = 179)	56 (n = 279)
Liver abnormalities	45 (n = 233)	59 (n = 326)
Spleen abnormalities	22 (n = 125)	9 (n = 59)
Kidney abnormalities	16 (n = 82)	24 (n = 135)

[1]External Lesions/Tumors include all body surface, head, eye and fin anomalies observed.

Appendix 2I. Fish Health Assessment Observations for the Rio Grande Silvery Minnow Health Study 2006-2008. [See Table 1 for site information and Appendix 2B for acronyms]

Plates 1-58. Rio Grande Silvery Minnow during Fish Health Assessments for the Rio Grande Silvery Minnow Health Study. All photography by Anne P. Davis/ USFWS.

July 2006:

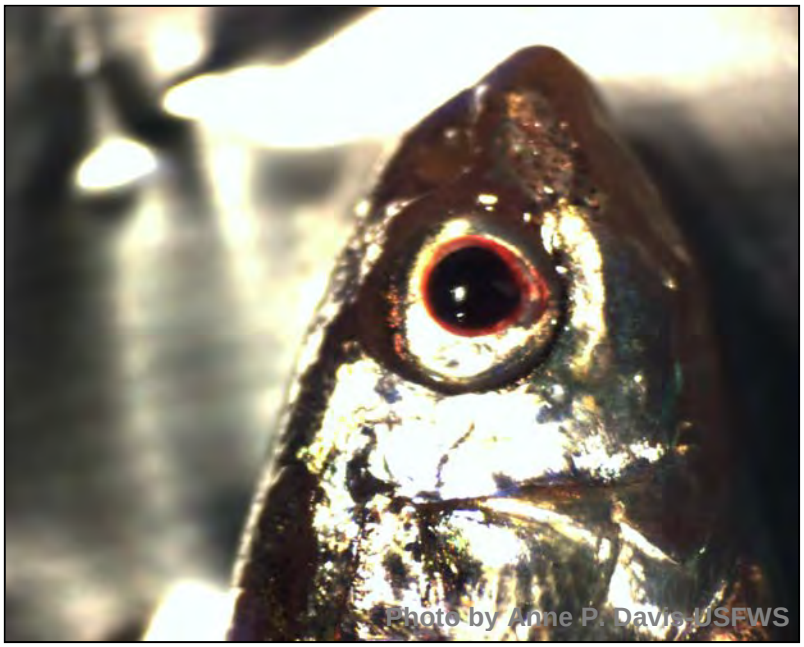

Plate 1. Fish 07/06/2-91. Hemorrhagic eye.

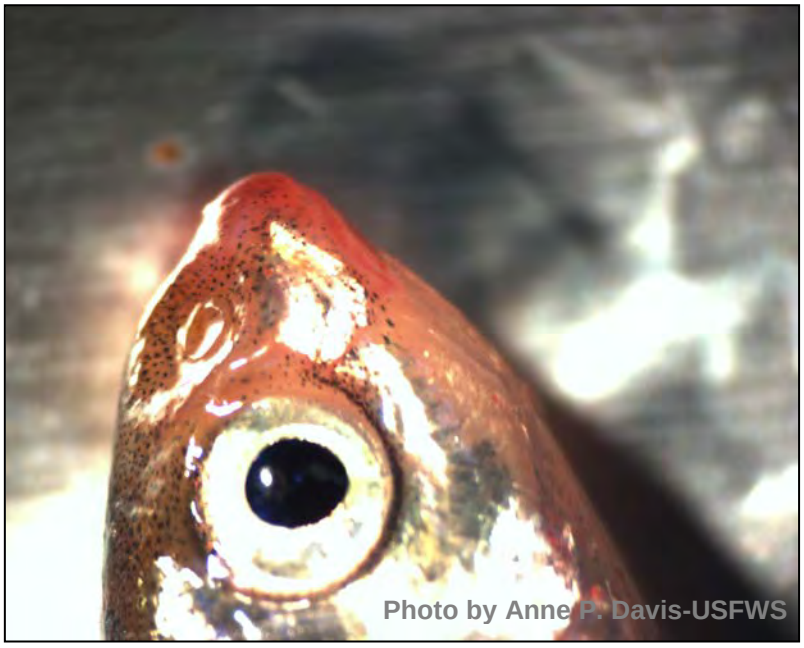

Plate 2. Fish 07/06/1-74. Swollen lip with lesion.

Plate 3. Fish 07/06/1-79. Shortened opercula.

Plate 4. Fish 07/06/5-88. Shortened opercula.

Plate 5. Fish 07/06/4-70. Frayed and deformed gills; reduced size.

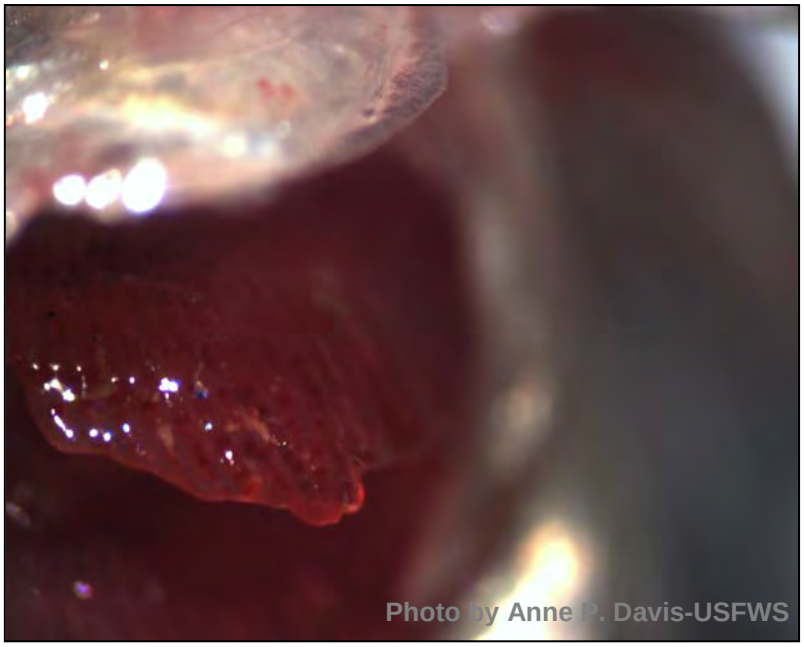

Plate 6. Fish 07/06/2-76. Spots on gills.

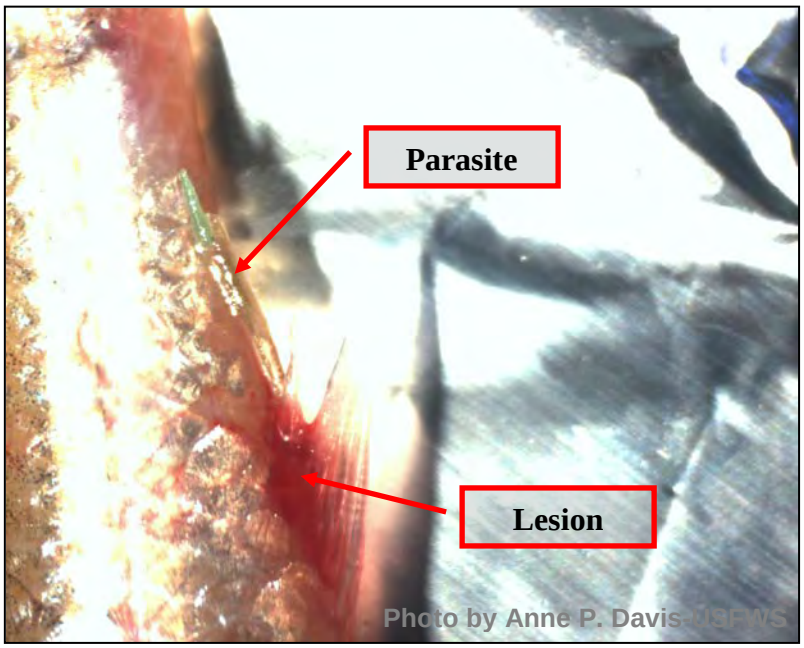

Plate 7. Fish 07/06/4-88. Parasite on dorsal fin; lesion at base of dorsal fin.

Plate 8. Fish 07/06/3-80. Dorsal fin lesion; VIE tag.

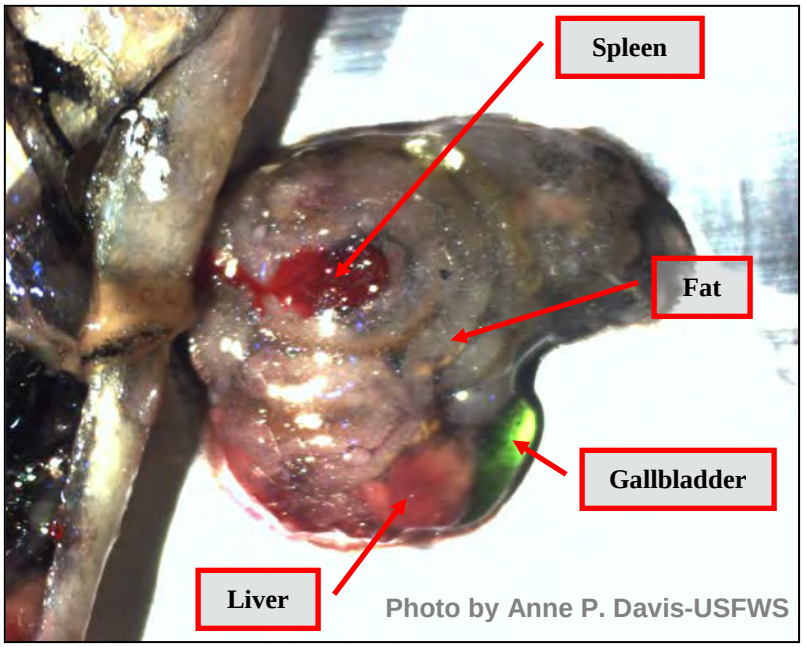

Plate 9. Fish 07/06/5-71. Viscera.

Plate 10. Fish 07/06/5-88. Viscera.

Plate 11. Fish 07/06/5-73. Female gonads.

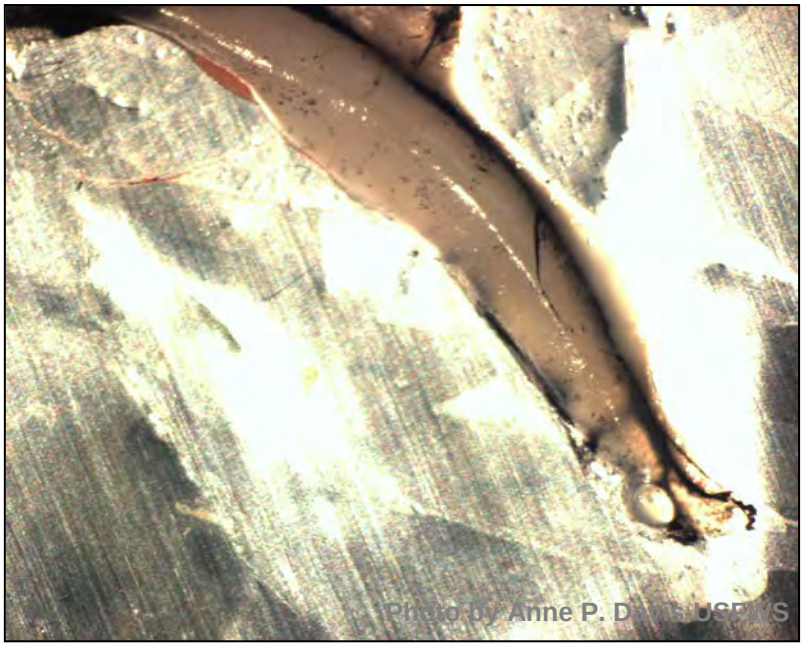

Plate 12. Fish 07/06/3-77. Male gonads.

October 2006:

Plate 13. Fish 10/06/1-87. Severely eroded caudal fin.

Plate 14. Fish 10/06/3-87. Severely eroded caudal fin.

Plate 15. Fish 10/06/4-73. Shortened opercula.

Plate 16. Fish 10/06/4-75. Shortened opercula.

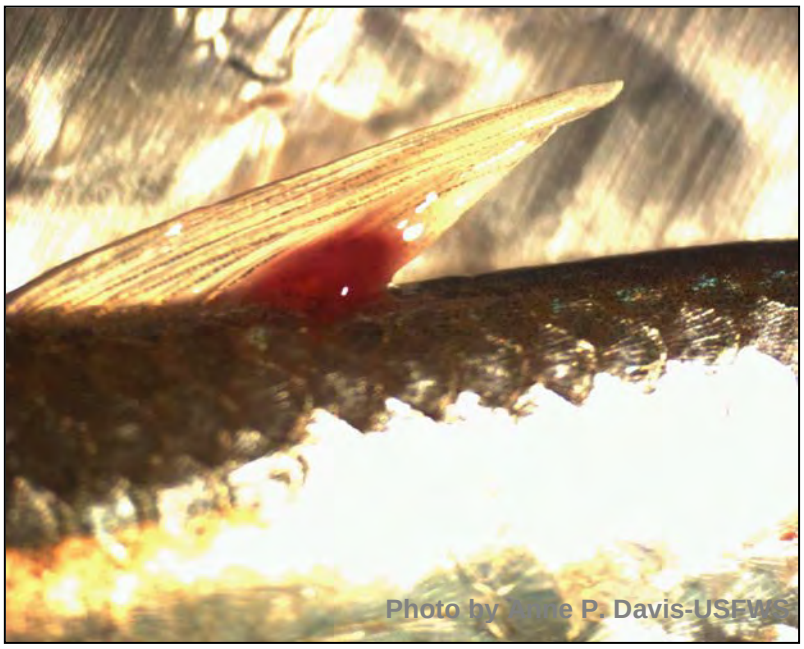

Plate 17. Fish 10/06/4-84. Dorsal fin lesion.

Plate 18. Fish 10/06/5-88. Caudal fin lesion.

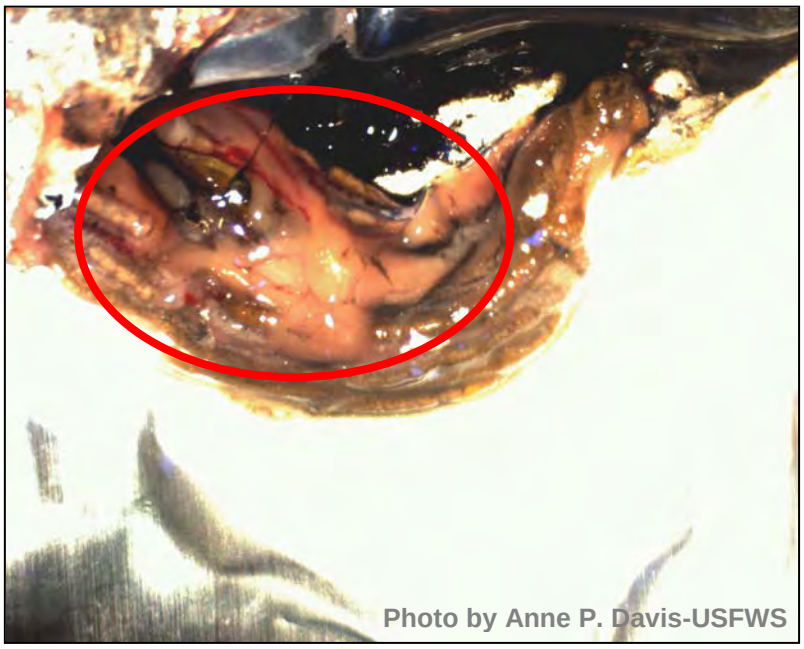

Plate 19. Fish 10/06/2-75. Tan (fatty) liver.

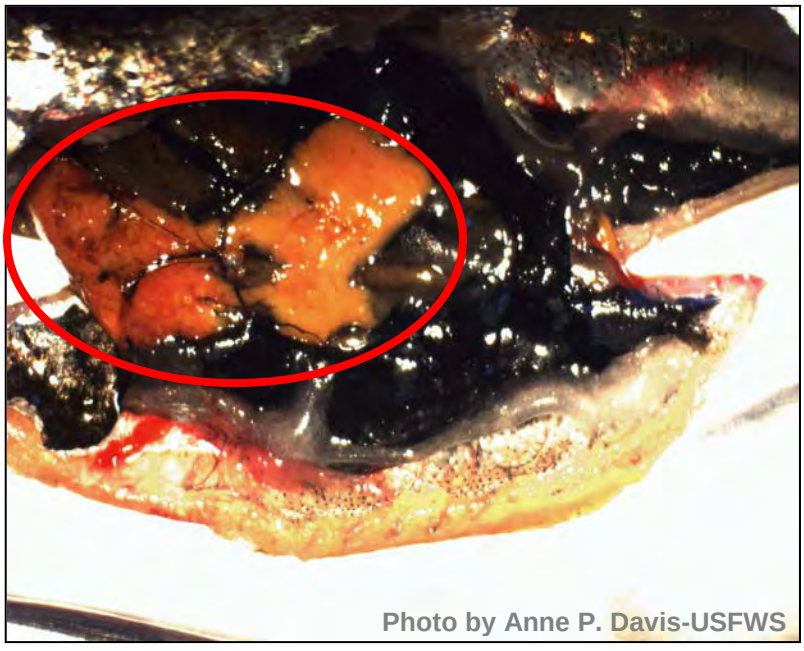

Plate 20. Fish 10/06/4-84. Discolored liver.

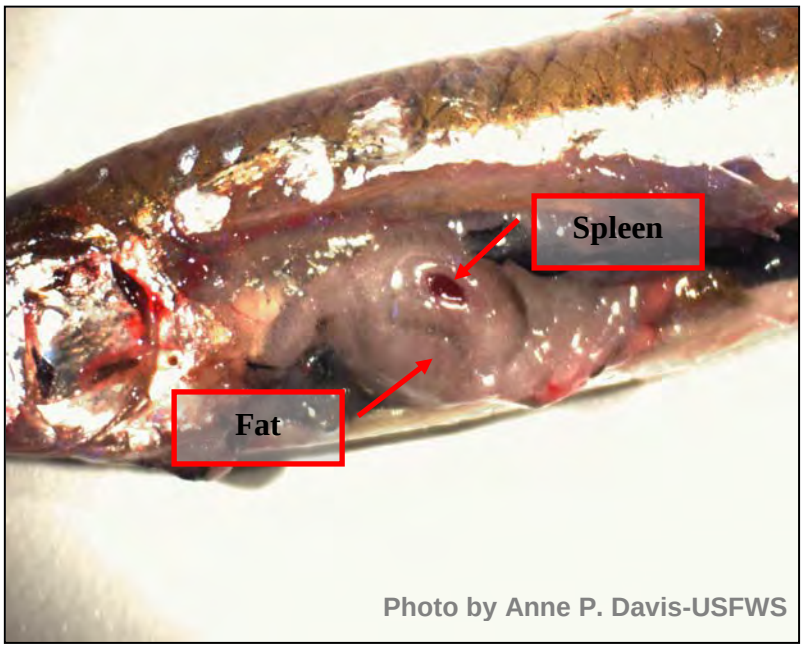

Plate 21. Fish 10/06/3-81. Mesenteric fat content; organs completely encased in fat.

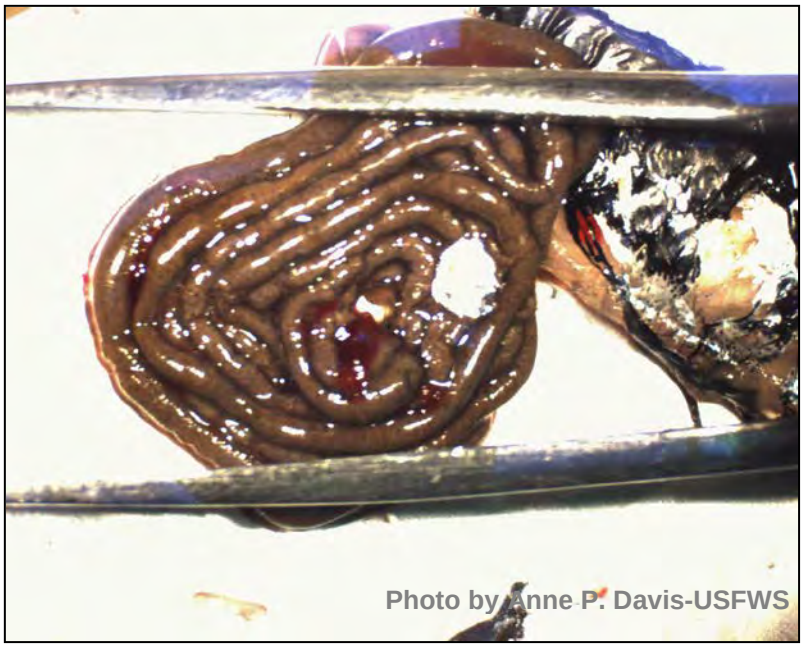

Plate 22. Fish 10/06/1-72. Full gut; no fat content.

Plate 23. Fish 10/06/5-70. Nodular spleen.

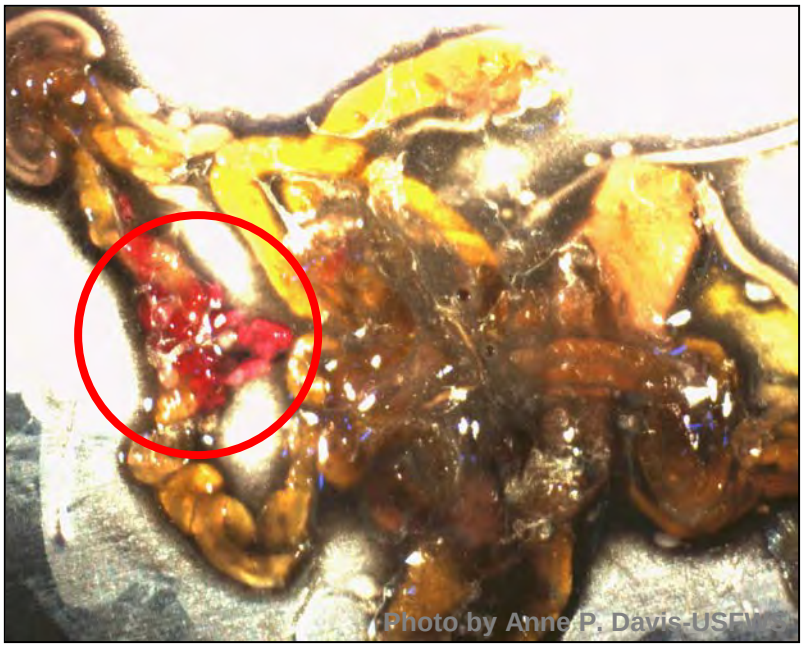

Plate 24. Fish 10/06/4-74. Nodular spleen.

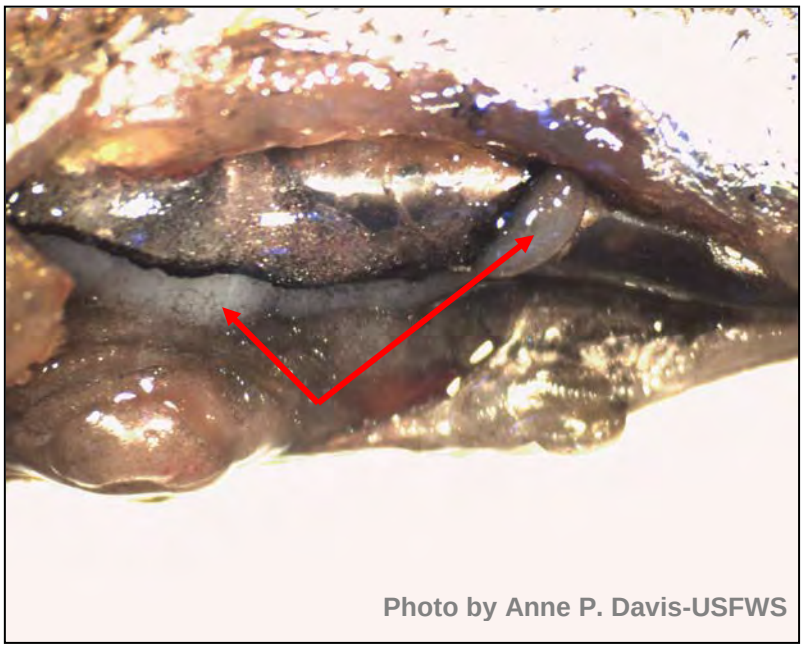

Plate 25. Fish 10/06/1-76. Male gonad tissue.

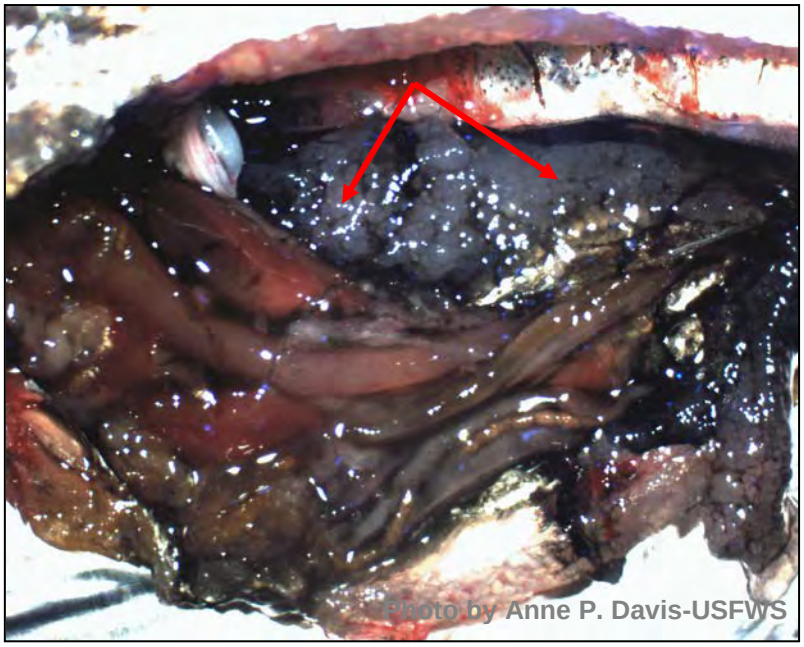

Plate 26. Fish 10/06/3-70. Female gonad tissue.

Plate 27. Fish 10/06/4-74. Swollen kidney.

Plate 28. Fish 10/06/5-76. Swollen kidney.

January 2007:

Plate 29. Fish 1/07/5-92. Severely eroded caudal fin with secondary infection.

Plate 30. Fish 1/07/3-84. Severely eroded caudal fin with secondary infection.

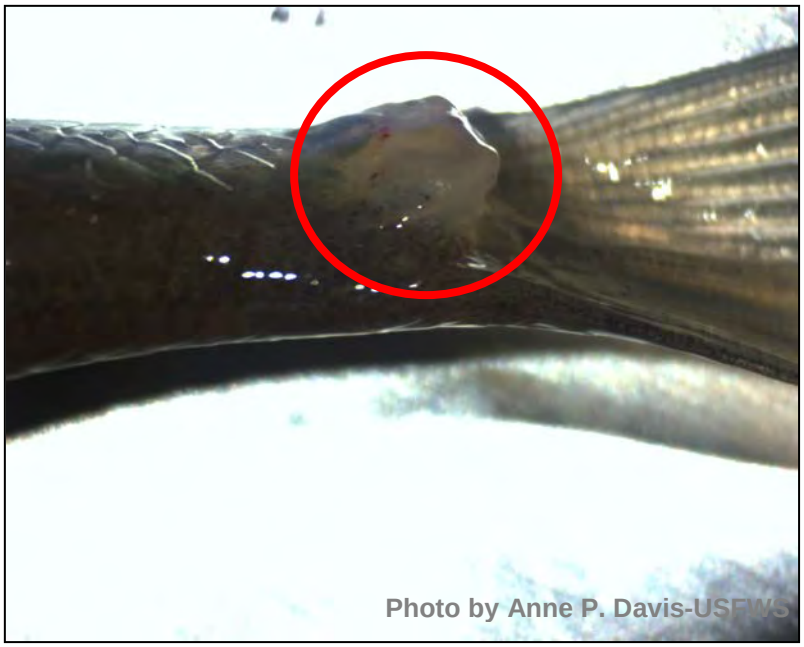

Plate 31. Fish 1/07/3-97. Tumor.

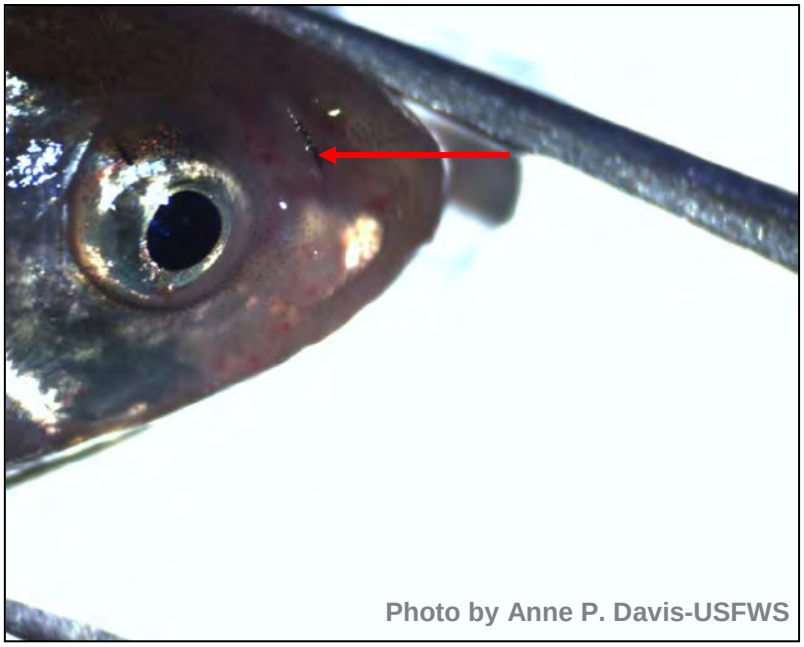

Plate 32. Fish 1/07/6-84. Parasite.

Plate 33. Fish 1/07/6-83. Pectoral fin lesion.

Plate 34. Fish 1/07/6-96. Anal fin lesion.

Plate 35. Fish 1/07/3-70. Shortened opercula.

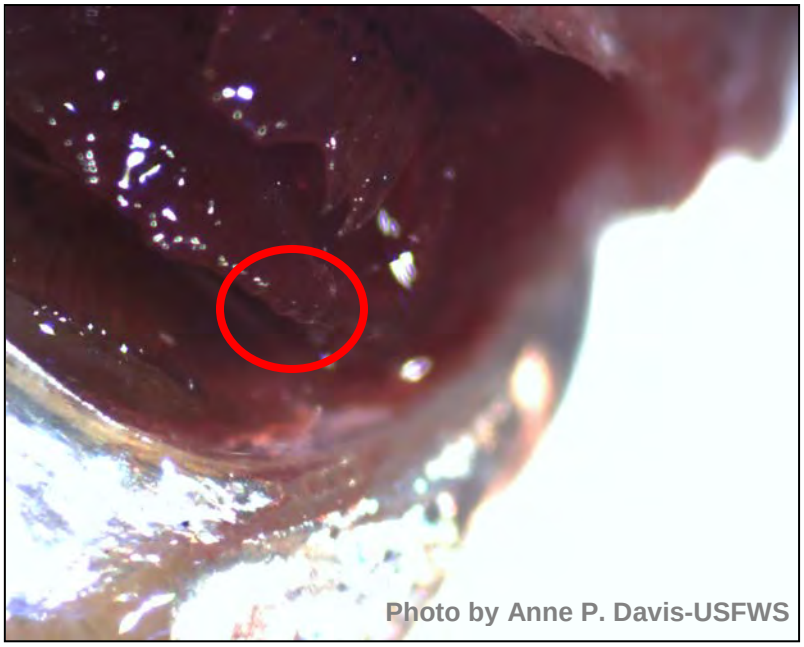

Plate 36. Fish 1/07/5-73. Clubbed gills.

Plate 37. Fish 1/07/5-95. Cysts (parasites) throughout mesentery.

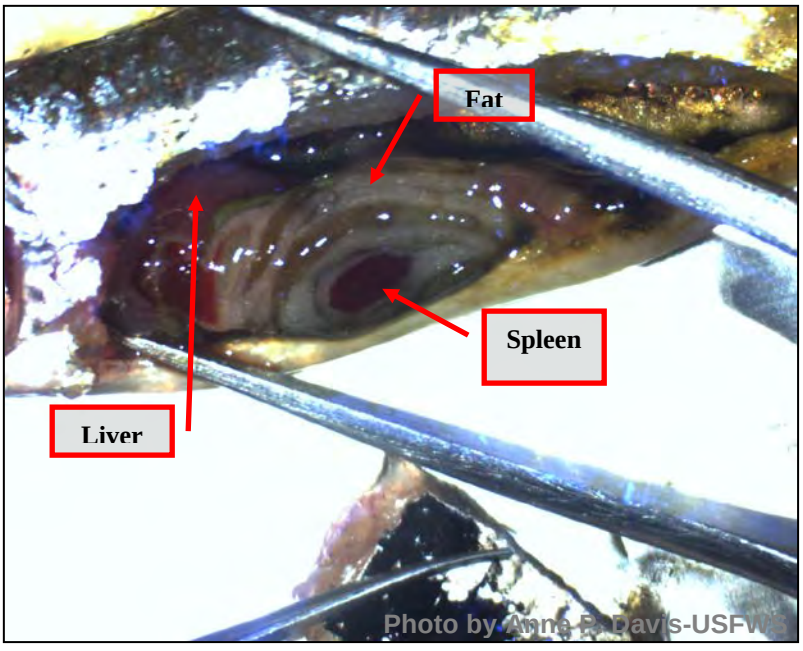

Plate 38. Fish 1/07/6-73. Viscera.

Plate 39. Fish 1/07/5-72. Eggs.

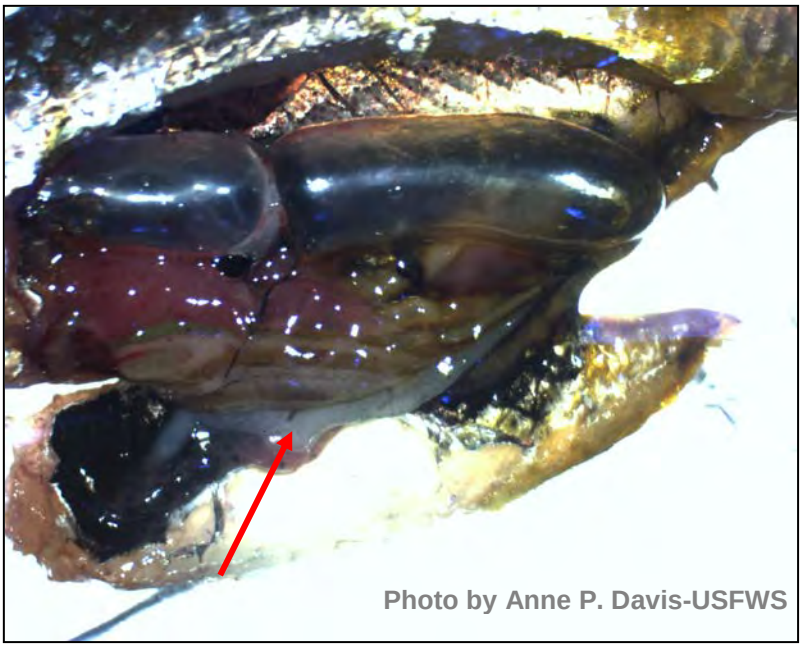

Plate 40. Fish 1/07/6-76. Male gonads.

April 2007:

Plate 41. Fish 4/07/4-83. Severely eroded caudal fin.

Plate 42. Fish 4/07/2-92. Hemorrhagic eye.

Plate 43. Fish 4/07/4-80. Lesion on upper lip.

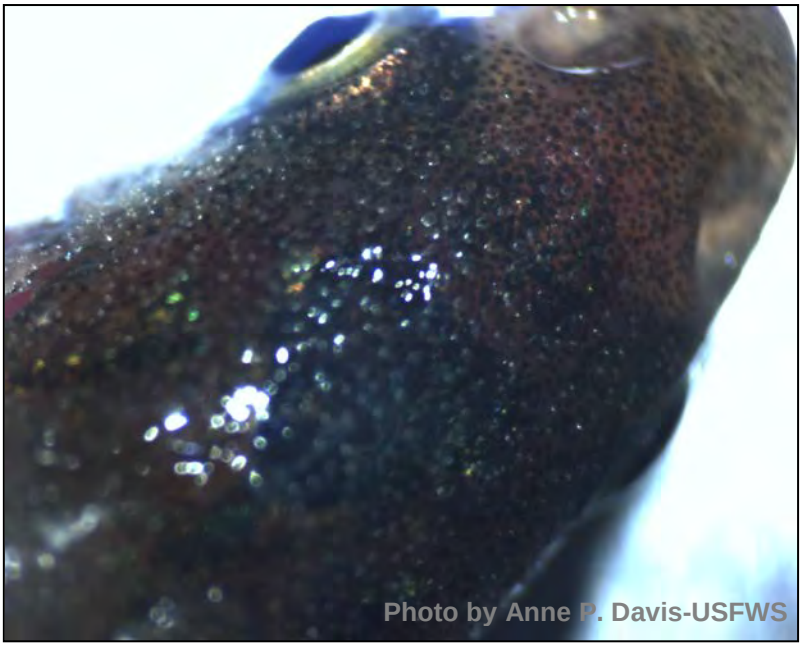

Plate 44. Fish 4/07/3-78. Tubercles.

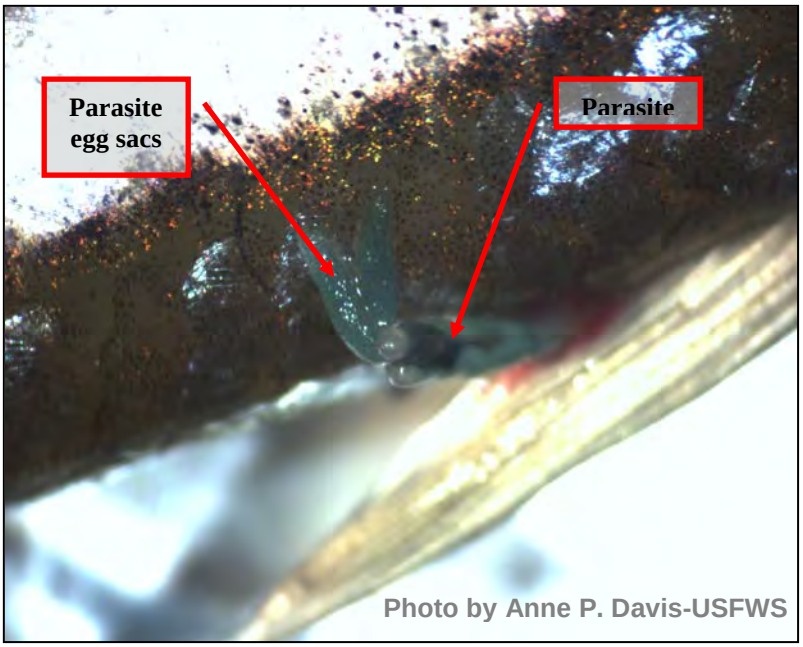

Plate 45. Fish 4/07/4-75. Parasite (with lesion at base of dorsal fin).

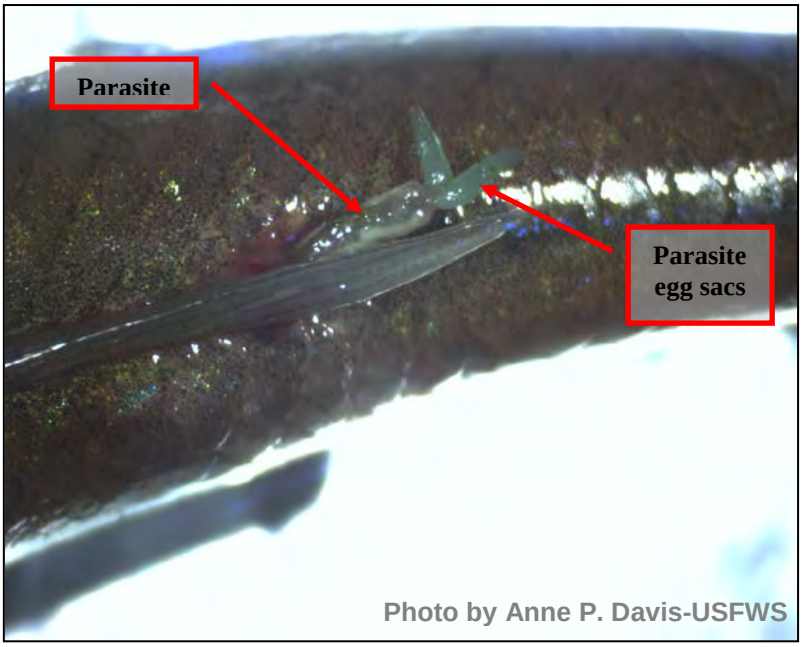

Plate 46. Fish 4/07/4-81. Parasite (with lesion at base of dorsal fin).

Plate 47. Fish 4/07/1-77. Shortened opercula.

Plate 48. Fish 4/07/5-75. Shortened opercula.

Plate 49. Fish 4/07/5-76. Shortened opercula.

Plate 50. Fish 4/07/5-84. Shortened opercula with lesion.

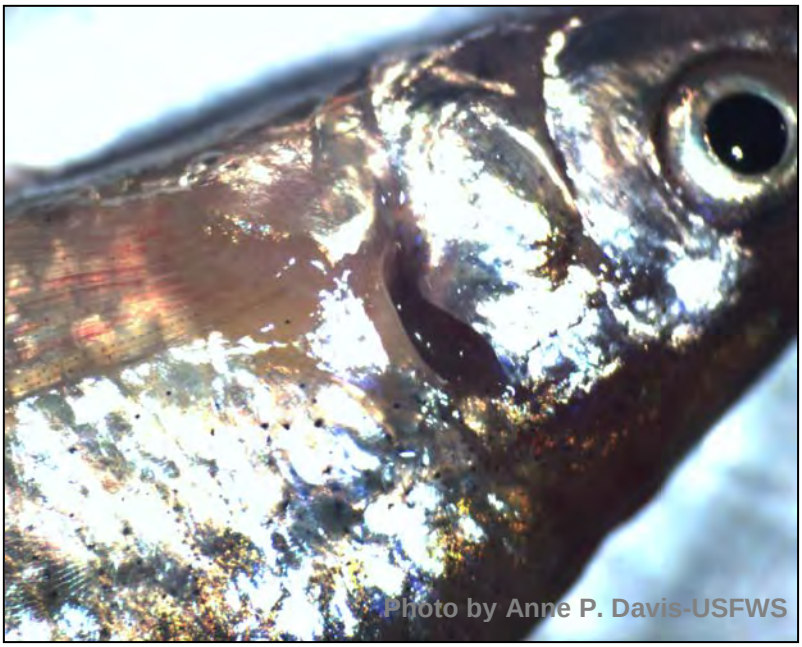

Plate 51. Fish 4/07/5-78. Shortened and deformed opercula.

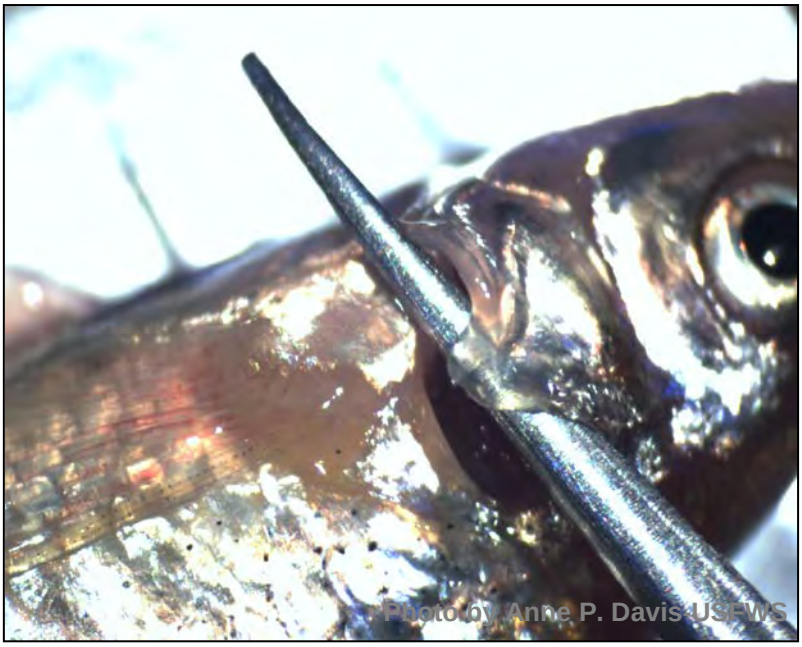

Plate 52. Fish 4/07/5-78. Shortened and deformed opercula detail.

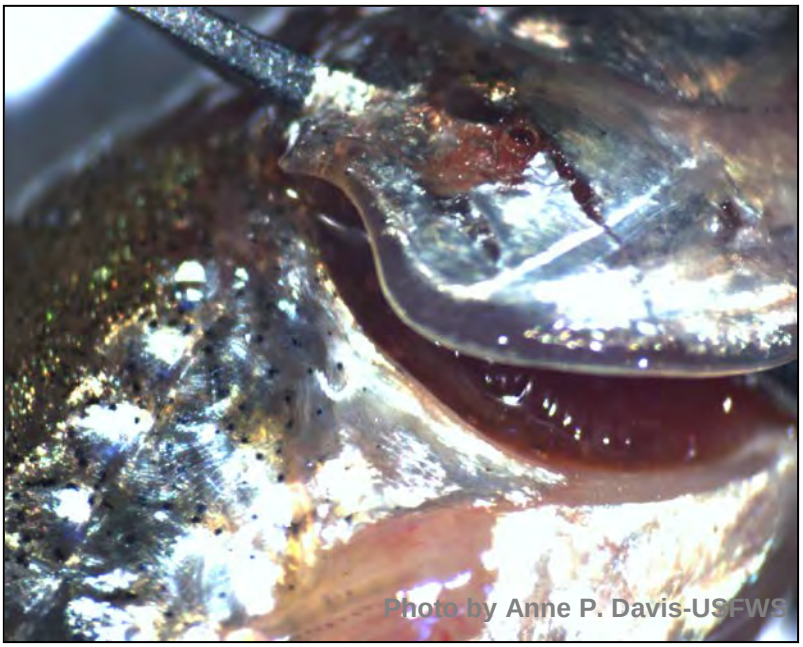

Plate 53. Fish 4/07/5-70. Shortened opercula.

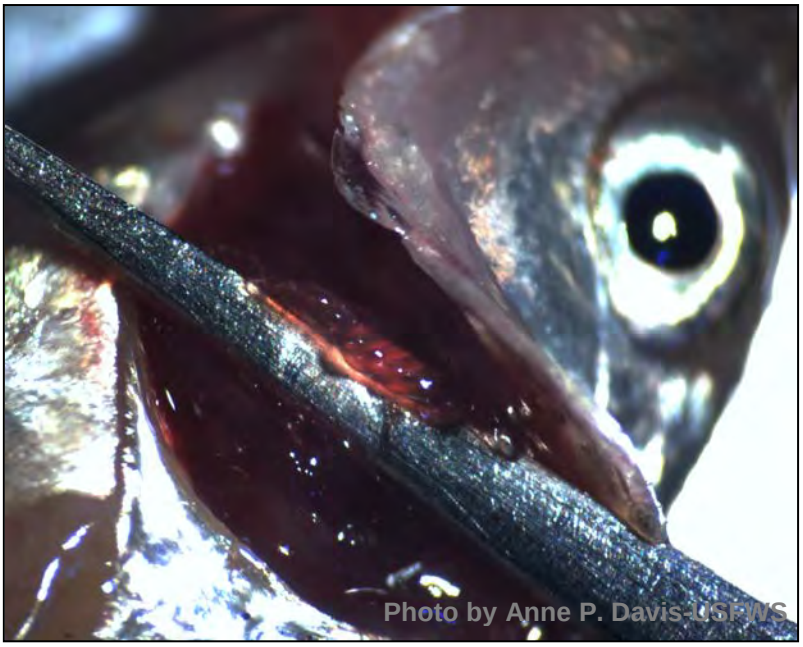

Plate 54. Fish 4/07/5-70. Clubbed gills.

Plate 55. Fish 4/07/3-73. Eggs.

Plate 56. Fish 4/07/5-72. Eggs.

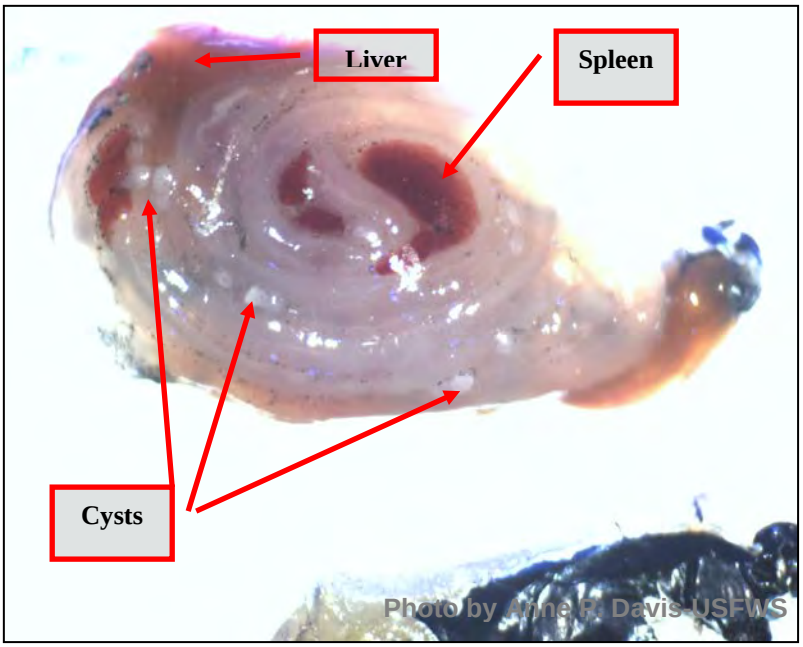

Plate 57. Fish 4/07/5-75. Viscera with cysts (parasites).

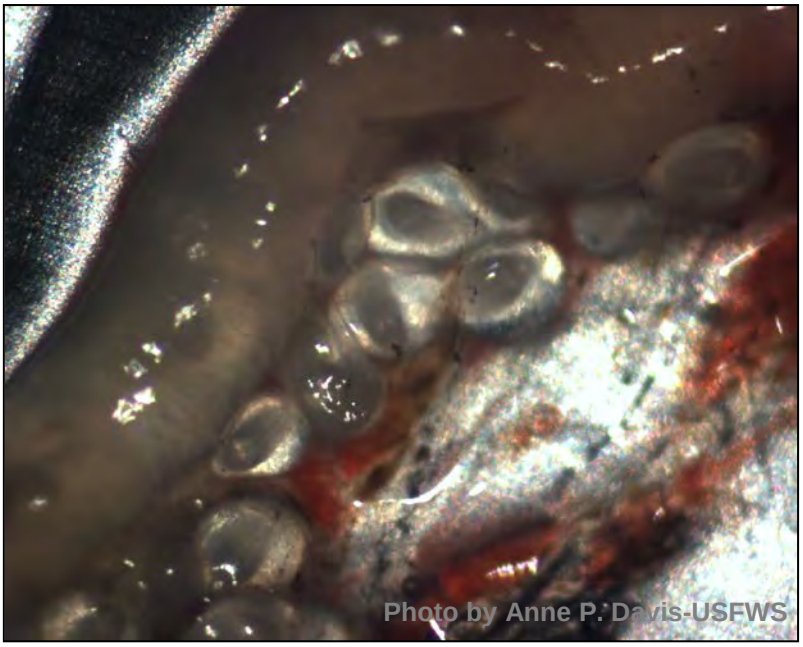

Plate 58. Fish 4/07/5-75. Cysts (parasites) detail.

March 2012

INTRODUCTION

The net accumulation of a chemical by an organism as a result of uptake from all environmental sources is termed bioaccumulation (USEPA 1995). Determining the extent of bioaccumulation in organisms is widely used as a method to monitor and assess pollutant distribution and bioavailability geographically and over time (Crawford and Luoma 1993; Schmitt et al. 1999). Phillips (1980), identified three benefits from using fish and other aquatic organisms in monitoring programs. First, concentrations of contaminants are often greater in tissue than in water and therefore, the probability of detecting trace amounts of contaminants in the environment is increased. Second, resident organisms provide a time-integrated assessment of a contaminant in question. Third, the direct bioavailability of contaminants that accumulate can be measured and temporally and spatially compared.

According to the critical body burden concept of McCarty (1986) and Escher and Hermens (2004), chemicals will have a specific effect (lethal or sublethal) upon fish once they have attained a specific internal tissue concentration. The internal concentration is independent of external influences and mode of exposure (i.e., in water or in the diet) and should occur at the same level regardless of the organism or species used. The objectives of this portion of the Rio Grande Silvery Minnow Health Study were to identify the body burden of chemicals in Rio Grande silvery minnow and review the extent of contamination, evaluate any possible health consequences associated with the concentrations, and provide baseline contaminant data. We analyzed Rio Grande silvery minnow carcasses (*Hybognathus amarus*; silvery minnows) for a variety of inorganic and organic chemicals, as well as lipid and moisture content. Organic chemicals analyzed included aliphatic hydrocarbons, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), dioxins and dibenzofurans, polybrominated diphenyl ethers (PBDEs), and a variety of organochlorine insecticides, including 1,1,1-trichloro-2,2-di(4-chlorophenyl)ethane, also known as DDT.

METHODS

Chemical Analyses, Quality Control and Methods of Interpretation of Contaminants in Fish

Lusk (2012) described the methods, dates, and locations of silvery minnow carcasses collected from six sites along the Rio Grande during 2006-2008. Study location and collection sites referred to in this report are described in Table 1 and depicted in Figure 1 and Figure 2. Silvery minnows that were dissected for fish health assessments (Davis and Lusk 2012) or pathogen assessments (Woodland 2012) were wrapped in aluminum foil or placed in polyethylene bags and frozen (4°Centigrade). Later, carcasses were removed from bags and foil and composited by site and date (up to 70 individual fish) in chemically clean jars and shipped frozen to the Service's contract laboratories for a variety of chemical analyses. These carcass composites (i.e., whole body minus the gonads or gills and some body fluids removed during their necropsy) were variously analyzed for 19 elements, methyl mercury, moisture and lipid contents, and 353 organic compounds including a variety of organochlorine (OC) pesticides, PCBs, PBDEs (flame retardants), dioxins, as well as aliphatic and aromatic hydrocarbons. A list of the chemicals and elements analyzed, abbreviations and names used, analytical methods used, and method detection limits for the chemical analyses, are provided in Table 2.

Briefly, silvery minnow carcass composites were homogenized and aliquot samples were digested and extracted for a variety of chemical analyses using gas chromatography, mass spectroscopy, atomic fluorescence or cold-vapor atomic absorption spectroscopy (Trace Element Research Laboratory 2010; Appendix 3A; and, TDI Brooks International, Inc., 2010; Appendix 3B). Percent lipid and percent moisture content were also determined. A single grab sample of water was also collected for analyses, and while the water and its results were not relevant to this study; however, the water sample provided for additional measures of laboratory quality control.

Quality-control measures included the analysis of method and procedural blanks (to measure contamination during sample preparation and analysis and to determine detection limits), duplicate samples (to measure precision), fortified (spiked) samples (to measure matrix interferences), and laboratory standards and certified reference material (to measure accuracy). Contaminants in silvery minnow carcasses are reported as micrograms per gram (µg/g; i.e., approximately parts per million) or micrograms per kilogram (µg/kg; i.e., approximately parts per billion) dry-weight and wet weight-weight concentrations; the latter was calculated from the moisture content of the sample.

Data Treatment and Statistics

Data were imported into spreadsheets (Microsoft Office Excel 2007, Microsoft Corp., Redmond, WA) or imported and analyzed using the statistical software Statistica (version 9.0, StatSoft, Tulsa, OK) or imported into a database using Microsoft Office Access 2007 (Microsoft Corp., Redmond, WA). Prior to final statistical analysis, the assumptions of normality and equal variance were formally tested by the Shapiro-Wilks test and Levene's test, respectively. Data that did not meet these assumptions were transformed to their natural logarithms and retested. If data were normally distributed comparisons were made using a one-way analysis of variance (ANOVA). Post-hoc comparisons between sites were conducted using a students' t-test (Bailey

1981) or Tukey's Honestly Significant Difference (HSD) test (for equal sample sizes) or Tukey-Spjotvoll/Stoline tests (for unequal sample sizes) (Statsoft Inc., 2010). If the natural log-transformation did not satisfy the assumptions, data were transformed to ranks and a Kruskal-Wallis and median test was applied to test the ranks (Statsoft Inc., 2010). Other parametric and nonparametric statistical tests were also employed and are so indicated in the text. For statistical purposes, as well as simplicity, when less than 25 percent of the analytical results were below the laboratory Method Detection Limit (MDL), the censored results were replaced with a value one-half the method detection limit prior to further statistical treatment. All censored data from comparison studies (e.g. Schmitt et al. 1999) were replaced with a value one-half the MDL (when reported) prior to comparison. Analytical results where chemicals were detected less frequently were only briefly summarized and results were provided in the appendices. Statistical significance probability (p) was set at $p < 0.05$ for all tests. Some of the fish tissue contaminant data were reported in either dry weight or wet weight concentrations and were so indicated. To convert dry weight concentrations into wet weight concentrations, the following equation was used:

Wet weight = (dry weight) * (1 - (percent moisture)/100)) Equation 1

Moisture content was determined by both inorganic and organic analytical laboratories. Values of moisture content conducted on same samples by the different laboratories were normalized and averaged. These average moisture contents were reported and evaluated. Only dry weight concentrations were reported by Mora (2001); therefore, a value of 72.1 percent moisture (average was derived using Schmitt et al. 1999) was used in Equation 1 to convert concentrations in lower Rio Grande fish into wet weight.

PCBs are a complex mixture of 209 isomers and congeners with 1 to 10 chlorines attached to the biphenyl structure in various arrangements with congeners identified by a suffix according to the nomenclature systems of Ballschmiter and Zell (1980) and Schultz and Malisch (1983). Aroclors are commercial PCB preparations that were produced up until 1977 by the Monsanto Chemical Company that contained various amounts of chlorine by weight. Total PCBs refers to the sum of the aroclors. Sum total PCBs refers to the summation of all PCB congeners and includes values where one-half the limit of detection (LOD) was substituted for PCB congener data below the LOD regardless of detection frequency. Certain PCB congeners are considered "dioxin-like" as they can have a fraction of the toxicity of dioxin (2,3,7,8-TCDD) and are often modified by their Toxic Equivalent Factors (TEFs; Van den Berg et al. 1998). TEFs from Van den Berg et al. (1998) for PCB congeners were used to calculate Toxicity Equivalents (TEQs) for fish. The TEQ scheme refers only to adverse effects (e.g., cancer) following interactions with the cellular Ah receptors (Wenning et al. 2011). For the purposes of the TEQ calculation, all values for dioxins, dibenzofurans, and PCB congeners below LOD were substituted with a zero.

Interpretation of Chemical Residues

Identification of contaminants of concern in whole body fish collected for this study was accomplished on a site or stream segment basis. Data from two sites each were combined into three groups (upper, middle, and lower) for further analysis at the segment scale. The evaluation methods included a comparison of the concentrations of chemicals in tissues collected from sites

or segments to various concentrations reported in the literature that affect fish (Jarvinen and Ankley 1999; USDI 1998; USACE 2010), to concentrations in fish collected from the Rio Grande or other watersheds (Roy et al. 1992; Simpson and Lusk 2000; Mora 2001; Abeyta and Lusk 2004; Schmitt et al. 2004; Buhl 2011), or to fish collected nationwide (Schmitt et al. 1999).

The significance of the concentrations of chemical contaminants in fish is not always clear, as elevated chemical concentrations are found in apparently healthy individuals. Identifying the presence of a chemical in silvery minnows was not considered sufficient information to conclude that the chemical would produce an adverse effect. The likelihood that a chemical substance in silvery minnows would produce an adverse effect is likely a function of the physical and chemical properties of the substance, the concentration of the chemical in the tissues, and the length of time the fish is exposed to the compound. Because environmental contaminants vary so widely in their potential to produce toxicity, comparison with an average literature-based contaminant-specific concentration was used to reach a determination regarding the potential for contaminant to produce adverse effects or identified the need for more research.

The Environmental Residue-Effects Database (USACE 2010 and references cited therein) were used for the majority tissue residue effects data comparisons. Emphasis was placed on contaminants that were known to pose serious health risks to fish or studies involving freshwater or marine fish in either carcasses or whole body fish in those studies cited in the USACE (2010) database. Those studies indicated concentrations above which a toxic effect due to a contaminant was likely to occur (i.e., adverse effects) including physiological, biochemical, growth, reproductive, and lethal effects. Those study also identify concentrations below which no adverse effects were likely to occur. For those cases where the concentrations in fish associated with adverse effects overlapped those concentrations where no adverse effects were identified, then comparisons were made to the average concentration associated with each type of effect (i.e., adverse or not). Where literature-based adverse effects thresholds were exceeded, then the corresponding adverse effect was further reviewed in relation to silvery minnow health.

Differentiating petrogenic from biogenic compounds in the interpretation of hydrocarbon residues in fish tissues is important. We compared the proportions of odd- and even-numbered long chain hydrocarbons to determine if sources were petrogenic (crude oil, diesel, light oil, etc.) as petrogenic compounds have approximately equal proportions of odd- and even-numbered long chain hydrocarbons (Hall and Coon 1988). We used ratios of pristane and phytane to n-heptadecane and n-octadecane, respectively, that when elevated indicate whether fish were recently or chronically exposed to petroleum compounds (Farrington et al. 1976; Anderson et al. 1978; Hall and Coon 1988).

RESULTS AND DISCUSSION

Quality Control of the Chemical Analyses

The U.S. Fish and Wildlife Service (USFWS) uses several contract laboratories to provide routine chemical analyses of chemical residues in biota and environmental samples (USFWS 2010a). The laboratories that conducted the chemical analyses of silvery minnow carcasses for this study were responsible for establishing the precision and accuracy of their analytical procedures. Quality assurance included cataloging silvery minnow sample collection, storage, and data transfer (Appendix 3C). Quality control procedures included analysis of procedural blanks, duplicate, and spiked samples as well as analysis of standard reference materials for inorganic chemicals (Appendices 3A and 3B). Data from such procedures were evaluated and documented by laboratory chemists and USFWS Analytical Control Facility (USFWS 2010a) and specific examples of quality control review are further described below.

Quality control described below was reviewed for the silvery minnow carcass samples only. Concentrations of mercury in the procedural blanks were slightly above the MDL in fish analyzed and reported by Trace Element Research Laboratory (2010; Appendix 3A). However, the concentrations of mercury detected in the procedural blanks (0.0028 µg/g dry weight) were within a factor of two of the MDL (0.002 µg/g dry weight) and were considered to be within the acceptable control limits. Concentrations of mercury in the procedural blanks were also 100 times less than the average concentration detected in silvery minnows and therefore were considered unlikely to affect interpretation. Concentrations in 10 of 41 duplicate element analyses of fish samples were below the MDL; thus no measure of the method precision was calculated. Quality control of analysis was maintained as the relative percent difference measured for the remaining 31 duplicate analyses averaged 6.1 percent with a range of 0 to 16.8 percent. Percent recovery of 41 spiked element analyses averaged 106 percent recovery with a range of 86 to 127 percent recovery of spiked amounts. Analysis of mercury in standard reference materials was within 87 to 107 percent of certified values, which indicated that mercury was accurately measured. Additional elements were analyzed in standard reference materials, and except for manganese (117 percent) and strontium (70.1 percent), the analysis of standard reference samples were within the acceptable range (80-110 percent) of certified values.

Concentrations of Aroclors (i.e., PCB-1242, PCB-1248, PCB-1254, PCB-1260) and PCB-total were detected in procedural blanks, but results were less than 10 times the MDL and were considered to be within the acceptable control limits (TDI–Brooks International, Inc. 2010; Appendix 3B). Concentrations in 91 of 224 duplicate analyses of fish samples were below the MDL and thus no measure of their method precision was calculated nor statistical analyses were conducted. The relative percent difference measured for the remaining 133 duplicate analyses averaged 6.3 percent with a range of 0 to 43.5 percent. Relatively high duplicate analysis results were found with biphenyl (43.5 percent) and heptachlor epoxide (29.1 percent); without these two duplicate analytes, the range of 131 duplicate analyses averaged 5.9 percent and ranged from 0 to 22.2 percent. Analysis of duplicate moisture content was 0 percent. Analysis of duplicate lipid content ranged from 0.7 to 12.6 percent and averaged 4.8 percent. All spike results for organic chemicals in silvery minnows were within normal limits (60 to 120 percent), except for

endosulfan II, n-heptacosane, and n-pentacosane, where the spike recoveries were low and therefore, the results of these three analytes may be biased low. As endosulfan II was not detected in greater than 75 percent of the samples analyzed, it was not further analyzed. Standard reference materials for organic chemicals were not analyzed as costs of analysis for over 350 organic chemicals in standard reference materials exceeded available funding.

Inorganic Contaminants, Methyl Mercury, and Lipid or Moisture Content

All analytical data on the concentrations of inorganic chemicals, methyl mercury or moisture content in silvery minnows are found in Appendix 3D and selectively summarized in Table 3. Nineteen inorganic contaminants were analyzed in carcass samples (Appendix 3D), however, molybdenum was below the MDL in all samples, and 4 elements (B, Be, Cd, and Cr) were detected in less than 75 percent of the samples analyzed. These 5 elements (B, Be, Cd, Cr, and Mo) were not compared statistically nor evaluated further. Concentrations of methyl mercury (MeHg) were also detected in all silvery minnows analyzed (Table 3). There were insufficient toxicity residue effects data available to assess the effects of iron, magnesium, manganese, and strontium in silvery minnows. The remaining inorganic contaminants in silvery minnows are discussed below. Average concentrations are provided below plus or minus one standard deviation (average±1SD).

A number of metals (Al, Cu, Fe, Mg, Mn, Ni, Pb, V, Zn) appeared to decrease in those fish collected on a downstream basis; however, this trend (or decrease) was not statistically significant (Table 3). Some of the differences in the metal contaminants in silvery minnows (Cu, Fe, Mg, Mn, Ni, Pb, V, and Zn) may partly be attributable to their ingestion of sediment (Buhl 2011). Silvery minnow feeding behavior from sediment substrates could increase their metal uptake by way of gill respiration or through dietary routes (Magaña 2009; Buhl 2011). Several of these elements were reported in underlying parent material (USGS 2008) and also generally decrease in a downstream direction. However, sediment samples reported by NMED (2009) collected near the same sites of fish collection did not show consistent or decreasing trends downstream for a number of elements (Cu, Fe, Mg, Mn, Ni, Pb, V, and Zn). Though three of these elements (As, Fe, and Mg) increased in water samples collected downstream (NMED 2009). Therefore, concentrations of these elements (Cu, Fe, Mg, Mn, Ni, Pb, V, Zn) in silvery minnows may reflect the general elemental composition of the geology around them, or reflect elevated sources, or reflect dietary exposures, which were not quantified by this study. Two elements (Cu and Ni) appeared to be elevated in silvery minnows collected near Site 2 (Table 3), though statistically insignificant in silvery minnows from other sites, this suggested there may be additional sources of copper and nickel near Site 2 as compared with other sites. Several heavy metals (Pb, Zn, Cu, Cr, As, Cd, and Ni) are common pollutants associated with urban stormwater (USEPA 1999), and Site 2 was below stormwater discharges from the Albuquerque urban area.

Aluminum

Aluminum concentrations in silvery minnow carcasses were elevated (82.3±75.0 µg/g wet weight), and although concentrations of aluminum generally decreased downstream, aluminum concentrations were not significantly different by site ($H=10.54$, $p=0.06$). Aluminum concentrations in silvery minnows (Table 4) were similar to aluminum concentrations in a

variety of fish collected from the Rio Grande by Roy et al. (1992; 45.3±60 µg/g wet weight), Mora (2001; 43.9±106.8 µg/g wet weight), or Schmitt et al. (2004; 16.1±11.6 µg/g wet weight), and to silvery minnows analyzed after 26 days accumulation in the Rio Grande (Buhl 2011; 15.1±7 µg/g wet weight). Aluminum concentrations in silvery minnows were similar to those in fish sampled from the San Juan River (Simpson and Lusk 1999; 152±193 µg/g wet weight).

Aluminum concentrations in whole fish associated with adverse effects (USACE 2010; average 32, range 8 to 77 µg/g wet weight) or with no effects (average 11, range 2 to 9 µg/g wet weight) ranged widely for freshwater fish (Cleveland et al. 1991; Handy 1993; Peterson et al. 1989). The majority of aluminum concentrations in silvery minnows were above the average concentration associated with adverse effects (32 µg/g wet weight). Interestingly, Poston (1991) showed no effects on growth, survival, or feeding in Atlantic salmon (*Salmo salar*) fed up to 200 µg/g wet weight dietary aluminum and salmon carcass concentrations reached 6 µg/g wet weight.

Sites that are acidic (i.e., with pH less than 7) and that have elevated aluminum in water can result in adverse effects to plants, invertebrates and fish (Sparling et al. 1997). Aluminum burdens in fish exposed to acidic conditions have been implicated in reduced growth and survival for both brook trout (Smith and Haines 1985) and smallmouth bass (Kane and Rabeni 1987). For example, adverse effects in Atlantic salmon occurred when aluminum concentrations of 20 µg/g wet weight were reached in fish when exposed to aluminum in water at a pH less than 5.0 (Peterson et al. 1989).

Aluminum is only sparingly soluble in water between pH 6 and pH 8 (ATSDR 2008). New Mexico Environment Department (NMED 2009) reported approximately 2 percent of aluminum was dissolved (0.1±0.2 mg/L) in the water column compared to the total concentration of aluminum (5.3±8.0 mg/L) in the Rio Grande. The minimum average pH in this study (Lusk 2012) was often slightly basic (pH>8) and few studies conducted have explored aluminum toxicity to fish in alkaline conditions. Considering that aluminum is often a gill toxicant and damage to the gill is greater in acidic water than in neutral or basic waters (Gensemer and Playle 1999), the toxicity residue relation for aluminum under acidic conditions in toxicity effect studies may not be representative of those under slightly basic conditions found in the Rio Grande.

It is also possible that a portion of the aluminum concentrations measured in silvery minnows may have come from ingested or sorbed sediment. Brumbaugh and Kane (1985) reported that whole-body aluminum concentrations in smallmouth bass (*Micropterus dolomieu*) were higher and more variable in fish analyzed with the gastrointestinal tract intact compared to those with the gut contents removed, presumably because of sediment in the gut.

Aluminum concentrations in silvery minnows as well as in other fish collected from the Rio Grande are at concentrations of concern and exceed adverse effect thresholds reported in literature-based studies associated with acidic conditions. Additional research should be conducted to determine if the elevated aluminum concentrations are associated with adverse effects in silvery minnows.

Arsenic

There was a significant difference in dry weight concentrations of (log transformed) arsenic (ANOVA, $F(5,27) = 4.60$, $p = 0.004$) in silvery minnows collected from among the six sites. Post hoc comparisons (using Tukey HSD test) indicated that average arsenic concentrations were highest in fish collected from Site 1 and Site 2 compared with those from Site 6 (Table 3). Arsenic concentrations in fish tissues often increased proportionately to increased dietary and water exposures and duration (Gilderhus 1966; Rankin and Dixon 1994; Buhl 2002). NMED (2009) reported arsenic dissolved in water samples collected near Site 1 (2.9±0.8 µg/L) and near Site 6 (4.4±1.3 µg/L). Between these two sites the average dissolved (log transformed) arsenic concentrations were statistically different ($t(25)=3.38$, $p=0.002$). Chapin and Dunbar (1994) reported that arsenic in the Rio Grande reflects the contributions of groundwater and the Jemez River, due to inputs of high-arsenic waters from the Jemez volcanic field. NMED (2009) reported arsenic concentrations in sediment samples collected near Site 1 (3.3±1.1 µg/g) or near Site 6 (4.0±2.2 µg/g), and while average arsenic concentrations generally increased downstream, they were not statistically different. This suggested that differential exposure to arsenic in water or sediment from these two sites might not reflect exposure and arsenic accumulation in silvery minnows collected from these two sites. Arsenic in silvery minnows may instead reflect dietary arsenic or other biological factors (Valette-Silver et al. 1999; Dutton and Fisher 2011).

Average arsenic concentrations in silvery minnow carcasses (0.9±0.1 µg/g wet weight, Table 4) were higher than average arsenic concentrations in a variety of fish collected from the Rio Grande by Roy et al. (1992; 0.2±0.5 µg/g wet weight), Abeyta and Lusk (2004; 0.2±0.2 µg/g wet weight), Schmitt et al. (2004; 0.2±0.1 µg/g wet weight), but similar to those in silvery minnows after 26 days accumulation (Buhl 2011; 0.6±0.2 µg/g wet weight). Average arsenic concentrations in silvery minnows were elevated compared to those in fish collected from the San Juan River (Simpson and Lusk 1999; 0.1±0.1 µg/g wet weight) and to those in fish collected nationwide (Schmitt et al. 1999; 0.2±0.3 µg/g wet weight). Depending on the form of arsenic in fish tissue, elevated arsenic in fish tissues from the Rio Grande may be appropriate for fish consumption advisories (Wilcox 1997). However, arsenic concentrations in silvery minnows were not considered high enough to represent a hazard to the fish itself, or piscivorous wildlife (Schmitt et al. 2004). For example, McGreachy and Dixon (1992) suggested a threshold for adverse effects of arsenic in fish occurred when concentrations exceeded 3 to 4 µg/g wet weight. Also, Gilderhus (1966) reported significant abnormal ovary and oocyte development occurred in adult fish at 1.7 µg/g wet weight, growth reduction occurred at 2.2 µg/g wet weight, and mortality occurred at 11.6 µg/g wet weight when compared with control fish. While elevated, arsenic in silvery minnows did not exceed levels of concern and likely reflected dietary sources.

Barium

There was a significant difference in the dry weight concentrations of barium (ANOVA, $F(5,27)=18.97$, $p=<0.05$) in silvery minnows collected from among the six sites. Post hoc comparisons (using Tukey HSD test) indicated that the average barium concentrations were highest at Site 1 and Site 2 and decreased significantly in fish collected downstream (Table 3). NMED (2009) reported barium concentrations in sediment samples collected near the upper sites (174±57 µg/g), near the middle sites (123±49 µg/g), or near the lower sites (170 ±49 µg/g); and

average concentrations were not statistically different. NMED (2009) reported barium concentrations in water samples collected near the upper sites (0.10±0.03 mg/L), near the middle sites (0.13±0.05 mg/L), or near the lower sites (0.18±0.14mg/L); and average concentrations were also not statistically different. Barium concentrations in silvery minnows did not reflect those in water or sediment, and also may reflect dietary concentrations. Barium is accumulated by several algal species, including diatoms and desmids (Havlik et al. 1980; Brook et al. 1988; Sedláček et al.1989). Diatoms are often part of the diet of larval and adult silvery minnows (Shirey 2004; Magaña 2009; USFWS 2010b).

Average barium concentrations in silvery minnows (15.5±4.8 µg/g wet weight,) appeared higher than average barium concentrations in a variety of fish collected from the Rio Grande by Roy et al. (1992; 2.9±2.5 µg/g wet weight,), Mora (2001; 3.5±5.4 µg/g wet weight) and Schmitt et al. (2004; 1.2±0.9 µg/g wet weight), but similar to those in silvery minnows after 26 days accumulation in the Rio Grande (8.7±3.6 µg/g wet weight) as reported by Buhl (2011). Barium concentrations in a variety of fish (other than silvery minnows) collected from the Rio Grande did not appear to differ from those in fish collected from the San Juan River (Simpson and Lusk 1999; 3.5±3.4 µg/g wet weight), from fish collected from the Colorado River (Hinck et al. 2006; 2.5±3.7 µg/g wet weight) or from fish collected nationwide (3.3±6.1 µg/g wet weight). Therefore, barium may also reflect a dietary exposure and accumulation in silvery minnows as compared with accumulation found in other fish collected from the Rio Grande and other watersheds. There were insufficient data available to assess the effects of elevated barium in silvery minnows. Additional research should be conducted to determine if elevated concentrations of barium in silvery minnows are associated with adverse effects.

Copper

Copper concentrations in whole fish associated with adverse effects (average 6.6, range 0.7 to 40 µg/g wet weight) or with no effects (average 5.1, range 0.02 to 16.3 µg/g wet weight) ranged widely and overlaps for freshwater fish (Handy 1992; Bonham et al. 1987; Jarvinen and Ankley 1999; Kamunde et al. 2005; Kolok et al. 2005). The majority of copper concentrations in silvery minnows (1.8±2.5 µg/g wet weight) were below the average concentration associated with adverse effects (6.6 µg/g wet weight). However, several high copper concentrations in silvery minnows collected from Site 1 and Site 2 (8.5-11.8 µg/g wet weight) were above this level of concern. Additional research should be conducted to determine if the elevated concentrations of copper are associated with adverse effects in silvery minnows at these sites.

Lead

Lead concentrations in whole fish associated with adverse effects (average 3.5, range 0.2 to 6.0 µg/g wet weight) or with no effects (average 1.3, range 0.2 to 6.0 µg/g wet weight) overlaps for freshwater fish (Hodson et al. 1978; Weber et al. 1991; Borgman et al. 1993). Lead concentrations in silvery minnows (0.1±0.1 µg/g wet weight) were below the average concentration associated with adverse effects (1.3 µg/g wet weight). However, silvery minnows collected in summer 2006 from Sites 1 through 4 had lead concentrations (>0.2 µg/g wet weight) greater than those found in trout associated with decreased iron concentrations in blood (Hodson et al. 1978). It was unclear why lead was elevated in silvery minnows during summer 2006, or

whether decreased iron may have occurred in silvery minnows that could reduce oxygenation and swimming performance (Hodson et al. 1978). Additional research could be conducted on the physiological effects of episodic or elevated lead concentrations in silvery minnows.

Mercury and Methyl Mercury

Methyl mercury averaged 88 (±10) percent of the total mercury in silvery minnows. While not statistically significant, mercury (Hg and MeHg) in silvery minnows (on a dry weight basis) appeared to increase downstream (Table 3). The highest concentrations of mercury (0.10 µg/g wet weight) were found in silvery minnows collected from Site 6. Wiener and Spry (1996) described concentrations between 0.01 and 0.1 µg/g wet weight as typical in fish collected from environments (without conditions such as low pH or warm temperature) that promote mercury accumulation. Beckvar et al. (2005) reviewed the available residue-effects literature and identified mercury concentrations less than 0.2 µg/g wet weight in whole body fish as protective. No silvery minnows exceeded this level of concern.

Nickel

Nickel concentrations in silvery minnows (range <0.1 to 3.6 µg/g wet weight) were highest in fish collected at Site 1 and Site 2 (Table 3). Few studies have been conducted evaluating the effects of nickel in whole fish (Jarvinen and Ankley 1999), but recently, Lapointe and Couture (2010) reported increased metabolic rates and enzyme activity in larval fathead minnow (*Pimephales promelas*) at whole body nickel concentrations greater than 2.6 µg/g wet weight. That is, elevated nickel exposure and accumulation increased energetic demand and metabolic costs in fathead minnows. While there may be differences between the species life histories, diet, contaminant exposure history, nickel concentrations measured in silvery minnows collected from Site 1 and Site 2 during summer 2006 suggest that they were at concentrations associated with increased metabolic rates in fathead minnows. Additional research should be conducted to determine the effects of elevated nickel concentrations in silvery minnows at upstream sites.

Selenium

While not statistically significant, selenium concentrations (on a dry weight basis) were elevated in silvery minnows collected near Site 5 (Table 3). Site 5 is below the confluence of the Rio Puerco, which drains a watershed that contains selenium-rich soils (Seiler et al. 1999). However, selenium concentrations in silvery minnows were less than the whole-body toxicity threshold of 4 µg/g dry weight advocated by Lemly (1996) and Hamilton (2002, 2003). Concentrations in silvery minnows were also lower than those linked with reduced growth (5.4 to 7.0 µg/g dry weight) in fathead minnows exposed to dietary selenium (Ogle and Knight 1989). Selenium concentrations in silvery minnows (0.5±0.1 µg/g wet weight) were similar to those in fish collected from the Rio Grande reported by Roy et al. (1992; 0.4±0.3 µg/g wet weight), Mora (2001; 0.3±0.2 µg/g wet weight), Abeyta and Lusk (2004; 0.8±0.7 µg/g wet weight), Schmitt et al. (2004; 0.7±0.4 µg/g wet weight), and in silvery minnows after 26 days accumulation (Buhl 2011; 0.8±0.2 µg/g wet weight), or in fish collected nationwide (0.5±0.5 µg/g wet weight).

Vanadium

Vanadium concentrations in silvery minnows ranged from 0.1 to 0.8 µg/g wet weight. No toxic threshold has been proposed for vanadium concentrations in fish, but Hilton and Bettger (1988) reported that a dietary toxic threshold to juvenile rainbow trout (*Oncorhynchus mykiss*). Reduced feeding and growth were seen in trout with carcass concentrations averaging 0.4 µg/g wet weight. At higher concentrations in trout (>5.3 µg/g wet weight), feed avoidance was increased, body weight was reduced, and mortalities were apparent (Hilton and Bettger 1988). Hilton and Bettger (1988) observed that the major physiological effect of vanadium in the trout was increased in vivo lipid oxidation. Silvery minnows from several upstream sites had vanadium concentrations above 0.4 µg/g wet weight when reduced feeding and growth were observed in trout. However, as the physiology of trout, a carnivore, and silvery minnow, an initial herbivore and later omnivore, may substantially differ, and there are few studies with which to compare, additional research should be conducted to determine whether growth or metabolic effects occur in silvery minnows associated with elevated vanadium residues.

Zinc

Average zinc concentrations in silvery minnows (38±6 µg/g wet weight) were similar to those in a variety of fish collected from the Rio Grande and reported by Roy et al. (1992; 33±16 µg/g wet weight), Schmitt et al. (2004; 39±24 µg/g wet weight), and in silvery minnows after 26 days accumulation (Buhl 2011; 50±18 µg/g wet weight), but higher than fish collected from the Rio Grande in Texas (Mora 2001; 13±13 µg/g wet weight). Zinc concentrations in a variety of other fish collected from the Rio Grande were similar to those in fish collected from the San Juan River (Simpson and Lusk 1999; 29±23 µg/g wet weight), in fish collected from the Colorado River (Hinck et al. 2006; 47±31 µg/g wet weight), and in fish collected nationwide (Schmitt et al. 1999; 39±24 µg/g wet weight).

Zinc concentrations in whole fish associated with adverse effects (average 58, range 5 to 220 µg/g wet weight) or with no effects (average 72, range 0.3 to 300 µg/g wet weight) ranged widely and overlapped in both marine and freshwater fish (Spehar 1976; Spehar et al. 1978; Farmer et al. 1979; Pierson 1981; Sherwood et al. 2000; Dube et al. 2005; USACE 2010). No zinc concentrations in silvery minnows were above the average concentration associated with adverse effect (58 µg/g wet weight). However, zinc concentrations in silvery minnows from all sites were higher than that (40 µg/g wet weight) associated with reduced growth in flagfish (*Jordanella floridae*) (Spehar 1976). Additional research should be conducted to determine if elevated concentrations of zinc are associated with reduced growth in silvery minnows.

Lipid and Moisture Content

Lipids are one of the main energy sources in fish. The stored energy available to a fish, as reflected in its body composition and energy reserves, may also influence its survival and reproduction (Breck 2008). Organic chemicals partition primarily into lipids within an organism and lipid content represents the capacity of an animal to accumulate those chemicals (Di Toro et al. 2000) as well as provides some resistance to chemical toxicity (Lassiter and Hallam 1990). However, when lipids are mobilized as an energy source, lipid-soluble chemicals tend to

partition from the lipid reserves into the bloodstream and increase the potential adverse effects on an organism (de Freitas and Norstrom 1974; Paterson et al. 2007). Lipid contents are often used to normalize organic pollutant concentrations, to reduce the variability within and between species and sexes, and normalization improves toxicity relationships for lipid soluble compounds when lipid and contaminant concentrations vary proportionally (Hebert and Keenleyside 1995).

Lipid content of silvery minnows ranged from 4.1 to 10.8 percent and averaged 6.9(±1.4) percent, but did not vary significantly by site or season or sample year (Table 5). However, lipid results may have been confounded by compositing fish of different size classes. Similar lipid content in fish collected from the Rio Grande was reported by Roy et al. (1992; 6.0±3.4 percent) and Schmitt et al. (2004; 4.5±2.9 percent) and in fish collected nationwide (Schmitt et al. 1999; 6.2±4.2 percent).

Moisture content in silvery minnows were not significantly different by site (Table 3). The average moisture content in silvery minnows in this study (71.9±1.9 percent) were similar to those in a variety of fish collected from the Rio Grande by Roy et al. (1992; 73.0±4.9 percent), Schmitt et al. (2004; 72.9±3.0 percent), and silvery minnows after 26 days accumulation (Buhl 2011; 73.0±1.7 percent), or in fish collected nationwide ((Schmitt et al. 1999; 72.1±4.5 percent).

A Pearson product-moment correlation coefficient was computed to assess the relationship between the moisture content and lipid content in silvery minnows. There was a significant negative correlation between the two variables ($r = -0.731$, $n = 27$, $p < 0.05$). This suggests that increases in moisture content are correlated with decreases in lipid content in silvery minnows and vice versa. Therefore, a relationship between lipid content and moisture content was modeled using linear regression analysis to predict lipid content:

Percent Lipid	= 78.6877 - (0.9945 * Percent Moisture)	Equation 2
Percent Moisture	= 45.2892 - (0.5366 * Percent Lipid)	Equation 3

If lipid content and moisture content are related as described by Equation 3, then a lipid content of 3 percent would translate to a moisture content of 78.8 percent; which would likely be the maximum moisture content of healthy silvery minnows. Mortalities occurred when lipid content was 3.2 percent or less in fish (Simpkins et al. 2003). Silvery minnows were not found to have lipid contents less than 3.2 percent.

Aliphatic and Aromatic Hydrocarbons

Analytical data for contaminant concentrations of organic chemicals and lipid content in silvery minnow carcasses are found in Appendix 3E and selectively summarized in Table 5. Three hundred and fifty-three organic contaminants were analyzed in carcass samples (Appendix 3E), however, 256 chemicals (73 percent) were detected in less than 75 percent of the samples analyzed, and therefore, those organic chemicals were not compared statistically nor evaluated further with the exception of n-undecane. However, all aliphatic hydrocarbons were used to help identify sources and interpret results. Several of the organic contaminants in silvery minnows are further discussed below.

Aliphatic Hydrocarbons

Aliphatic hydrocarbons (1.2±2.9 µg/g wet weight) were detected in all silvery minnows collected from five sites during January 2008 (Appendix 3E, Table 5). Differentiating petrogenic from biogenic compounds is important to demonstrate a pathway between the sources of hydrocarbons and their deposition in fish tissues. In general, the origin of organic matter can be obtained by analyzing the composition of aliphatic hydrocarbons, their peaks and ratios, or through the composition of the carbon preference index (Bray and Evans 1961). None of the hydrocarbons detected in silvery minnows had equal proportions of odd- and even-numbered aliphatic hydrocarbons indicative of petrogenic sources such as oil spills (Hall and Coon 1988). Also, all ratios of pristane-to-n-heptadecane or phytane-to-n-octadecane were low in silvery minnows, indicating no recent or chronic exposure to petroleum compounds in their diet (Anderson et al. 1978, Farrington et al. 1973, Hall and Coon 1988). Pristane-to-phytane ratios were also low (0.73±0.03), except at Site 1 (>1.1), which indicated that petrogenic aliphatic hydrocarbons were not those present in silvery minnows. Petrogenic hydrocarbons have much lower pristane-to-phytane ratios ranging from 0.14 to 0.36 (Roushdy et al. 2010). Pristane-to-phytane ratios (approximately 0.8) are indicative of carbonate-dominated habitats (ten Haven et al. 1987).

The presence of aliphatic hydrocarbons with a maximum of 20 to 35 carbons and with dominance of odd numbers of carbon atoms can be used to indicate the prevalence of higher land plant waxes though source identification is not always certain (Tornabene 1980**;** Cranwell 1984; Jeng and Huh 2008). By using the presence of higher chain hydrocarbons, we estimated that 34 and 39 percent of the aliphatic hydrocarbons in silvery minnows at Site 3 and Site 4 were from terrestrial plant sources. Up to 12 percent of the aliphatic hydrocarbons in silvery minnows at Site 1 were from terrestrial plant sources; whereas, silvery minnows from Site 2 and Site 6 contained less than 5 percent of aliphatic hydrocarbons of terrestrial plant origin.

The contribution of phytoplankton and diatoms in silvery minnows can be difficult to recognize due to the low abundance of aliphatic hydrocarbons in certain species of algae (Tornabene 1980). However, significant amounts of 15, 19, and particularly 17 carbon chain aliphatic hydrocarbons, has been interpreted as an indicator of hydrocarbons of algal origin (Cranwell 1984; Jeng and Huh 2008). Using these carbon chain aliphatics as indicators, silvery minnows collected in January 2008 at Site 2 and Site 6 contained approximately 92 and 91 percent of aliphatic hydrocarbons from algal origin; whereas silvery minnows at Site 1 contained 28 percent; and, silvery minnows at Site 3 and Site 4 contained approximately 60 percent of aliphatic hydrocarbons from algal origin. These hydrocarbon indicators suggested a wide variety of plant materials can be present in silvery minnows at different locations and during different seasons.

Silvery minnows in January 2008 collected from Sites 2 though 6 contained 5 percent (or less) of petrogenic aliphatic hydrocarbons (that is, they had few aliphatic chains with less than 15 carbons associated with oil, gasoline, or diesel fuels) (Neff 1979). However, silvery minnows collected at Site 1 contained an inordinate amount of n-undecane (18.5 µg/g wet weight) with over 58 percent of their hydrocarbon burden being indicative of petrogenic origin. This is the highest concentration of n-undecane ever reported in freshwater fish. N-undecane is indicative of diesel range organic compounds such as kerosene-based fuels, solvents, paints, and soot

(Technical Resources International, Inc. 2003), perhaps from idling traffic on the 550 Bridge above Site 1, or from other unknown sources nearby.

Aromatic Hydrocarbons

A variety of aromatic hydrocarbons were detected in silvery minnows (total PAHs were 66±11 µg/kg wet weight) from five sites collected in January 2008 (Table 5, Appendix 3E). PAHs are found everywhere in the environment and are formed by burning organic matter (Neff 1979; Eisler 1987). PAHs are commonly found in used motor oil, exhaust from internal combustion engines and emissions from fossil fuel powered energy plants, grilled foods, forest fires, and volcanoes, as well as most products made from coal and petroleum (National Research Council 1983; Eisler 1987). PAH concentrations in freshwater varies widely, depending upon such factors as proximity of the waterbody to the source, source type, and season. PAH concentrations in fish depend upon their proximity to the source of pollution, the physical and chemical properties of the PAH molecule, environmental variables, the PAH content of the diet, and biological factors (Moore and Ramamoorthy 1984; Eisler 1987; McElroy et al. 1989).

Several PAHs, especially those containing 4 to 6 aromatic rings in their structure, have been shown to be mutagenic, carcinogenic, and inducers of tumors in animals exposed to high doses of PAHs in the laboratory. Studies directly linking PAHs to these effects in wild fish are few in number (Albers 2003). From studies conducted in the Great Lakes basin, the International Joint Commission recommended that concentrations of the PAH benzo[a]pyrene not exceed 1.0 µg/g in fish. Average PAH concentrations in silvery minnows (1.5±2.6 µg/kg wet weight) were nearly 10 times lower than this threshold of concern. Concentrations of PAHs in silvery minnows tended to reflect the patterns of PAHs in sediment samples (NMED 2009) with higher concentrations detected at the middle sites near Albuquerque, New Mexico (Table 5).

Certain PAHs, particularly naphthalene and its alkylated derivatives, such as 1-methyl-naphthalene, 2-methylnaphthalene, 2,6-dimethylnaphthalene, C1-methylnaphthalene, C2-naphthalene, C3-methylnaphthalene, C4-methylnaphthalene, but also phenanthrene, fluor-anthene, and fluorene, were relatively elevated in silvery minnow carcasses compared to the other PAHs (Table 5, Appendix 3E). Many of these PAHs either components of weathered oil or were combustion-related hydrocarbons. For example, combustion related hydrocarbons such as phenanthrene and its derivatives averaged 2.7 percent, fluoranthene and its derivatives averaged 1.4 percent, chrysene and its derivatives averaged 0.7 percent, and pyrene and its derivatives average 0.6 percent of the total PAHs measured in silvery minnows. Naphthalenes and its derivatives were the highest percentage (average 6 percent) of the total PAHs measured in silvery minnows. Biphenyl occurs in weathered coal tar, crude oil, and natural gas and averaged 4 percent of the total PAHs measured in silvery minnows.

Naphthalene and its alkylated derivatives were consistently detected in silvery minnows (15±2 µg/kg wet weight) (Table 5). Naphthalenes are not generally reported in fish, but were detected at concentrations below 3 µg/kg wet weight in fish from the Pacific Coast (Easton et al. 2002). Naphthalene is a white solid with a strong smell and is also called mothballs. Naphthalene is a component of fossil fuels such as gasoline, diesel, oils and coal; it is also formed when natural products such as wood or tobacco are burned. Naphthalene has a short half life in water.

Naphthalene derivatives were detected at low concentrations in sediment samples collected by the NMED (2009) from Site 3 (5.6 µg/kg wet weight) and were less than naphthalene sediment toxicity thresholds (Buchman 2008) . Notably, the pattern of accumulation of naphthalene and its derivatives was similar in silvery minnows collected along the Rio Grande suggesting exposure to widespread atmospheric sources of PAHs (Table 5).

High concentrations of PAHs in fish have been associated with decreases in health measures, increased lesions, increased genetic alterations, and altered populations (Albers 2003). PAHs in fish tissues from uncontaminated areas were generally less than 10 µg/kg wet weight and from contaminated areas were generally greater than 100 µg/kg wet weight (Eisler 1987). PAHs in fish are usually low because fish rapidly metabolize PAHs or excrete them, though there is a metabolic cost associated with the increased enzyme activity (Albers 2003; Colavecchia et al. 2004). Therefore, silvery minnows were considered moderately contaminated with PAHs (average total PAHs 66±11 µg/kg wet weight). However, effects of PAHs in silvery minnows are difficult to generalize as the incidence of lesions, effects of any genetic alterations and metabolic pathways of PAHs in fish varies by species (Albers 2003). Additionally, few studies have been conducted on wild fish (Albers 2003). Additional research should be conducted to determine the growth effects or lesions associated with elevated PAHs in silvery minnows.

Organochlorine (OC) Pesticides, Dioxins, PCBs, and PBDEs

A variety of OC pesticides (total OCs 54±26 µg/kg wet weight) were detected in silvery minnows collected variously from all six sites during 2006 to 2008 (Table 5, Appendix 3E). The DDT metabolite, p,p'-DDE, accounted for the majority (43±14 percent) of the sum total of the OC pesticides detected in silvery minnows. Trans-nonachlor (11±4 percent), alpha chlordane (9±4 percent), and endosulfan sulfate (6±2 percent) were also detected at greater concentrations than the remainder of the OC pesticides (<1 to 5 percent) and are discussed below.

Total DDTs

DDT became widely used in the 1940s and was extremely effective controlling pest vectors until it was banned by the USEPA in January 1973 due to its long residual life in the environment and its accumulation in food chains (Beckvar and Lotufo 2011). The term total DDT refers to the sum of DDT and its metabolites (DDE, DDD, and DDMU), including the ortho para (o,p' or 2, 4) and para para (p,p' or 4, 4) isomers. Total DDT in silvery minnow carcasses was mostly DDE (83 percent), DDD (12 percent) and DDMU (3 percent). However, approximately 2 percent of the parent chemical (DDT) was still detected suggesting use of DDT in the environment and transport to the Rio Grande watershed has not ceased. Similar proportions of DDT (8 percent) and its metabolites DDE (80 percent) and DDD (13 percent) were reported in fathead minnow by Jarvinen et al. (1976).

Average concentrations of total DDT in silvery minnow carcasses (18±7 µg/kg wet weight) were similar to those found in fish sampled throughout the Rio Grande (Schmitt et al. 2004; 43±16 µg/kg wet weight), but generally less than those found in fish sampled nationwide (Schmitt et al. 1999; 240±800 µg/kg wet weight). No significant linear relationships was found between the concentrations of total DDT in silvery minnows and their lipid content. An ANOVA tests found

significant differences in wet weight concentrations of total DDT ($F(2,9)=14.2$, $p=0.002$) in silvery minnows collected from the middle sites (Site 3 and Site 4) than in those collected from the upper (Site 1 and Site 2) or lower sites (Site 5 and Site 6). As there are no known sources of total DDT near Site 3 and Site 4, it is possible that the rate of bioaccumulation or diet of silvery minnows is greater in this section of the river. Concentrations of total DDT in silvery minnows were below the lethal effects threshold of 600 µg/kg wet weight reported by Beckvar and Lofuto (2011). However, recent research have focused on endocrine disruption and other sublethal effects that have been observed at concentrations of total DDT similar to and up to two orders of magnitude lower than in lethal studies with older fish life stages (Beckvar and Lofuto 2011). Therefore, additional research could be conducted to determine if total DDT detected in silvery minnows are associated with any adverse sublethal effects.

Endosulfan

Designed in the 1950s, endosulfan is an organochlorine insecticide that can be used on a wide variety of vegetables, nuts, fruits, cotton, and ornamental plants. Endosulfan is a member of the class of the cyclodiene pesticides and consists of two isomers (endosulfan I and II), and a sulfur metabolite (Beckvar and Lotufo 2011). Endosulfan was recently banned in the United States due to continued risk to farm workers, wildlife, fish quality, and the environment, with a complete phase out of agricultural use of the chemical by 2016 (USEPA 2010).

Concentrations of endosulfan sulfate in silvery minnow carcasses (2.4±1.5 µg/kg wet weight) were higher than endosulfan concentrations in larger-bodied fish (< 0.2 µg/kg wet weight) collected from the Rio Grande by NMED (2009). No significant linear relationship was found between concentrations of endosulfan in silvery minnows and their lipid content. There was a significant positive relationship ($r = 0.668$, $n = 10$, $p = 0.017$) between concentrations of endosulfan sulfate in silvery minnows and their average weight in composite samples. However, average weights of the composited fish were not significantly different by site or by section of river, even though some of the larger fish were in collections of fish from Site 3 and Site 4. An ANOVA test found significant differences in carcass wet weight concentrations of endosulfan sulfate ($F(2,9)=13.6$, $p=0.001$) collected from the middle sites (Site 3 and Site 4) than in those collected from the upper or lower sites (Table 5). The NMED (2009) sampled endosulfan in sediments collected from the Rio Grande during 2006 to 2008, and three of the highest concentrations (0.05 µg/g wet weight) were found in the Rio Grande near Site 3. Reasons for elevated endosulfan sulfate in silvery minnows from the middle sites are unclear. There were elevated sediment concentrations of endosulfan sulfate near Site 3, but also bioaccumulation rates or diets in silvery minnows from the middle sites may differ in this river section.

Several fish species experienced mortality associated with whole body concentrations of endosulfan sulfate as low 31 µg/kg wet weight (Beckvar and Lotufo 2011). Morphological changes in the liver and enzyme activity reductions in brain, liver, and skeletal muscle were reported in fish at concentrations as low as 1 µg/kg wet weight, becoming more severe at concentrations greater than 5 µg/kg wet weight (European Food Safety Authority 2011). As concentrations of endosulfan and endosulfan sulfate in silvery minnows exceeded levels of concern, particularly in those collected from Site 3 and Site 4, additional research should be conducted to determine the effects of elevated concentrations in silvery minnows.

Trans-nonachlor

Trans-nonachlor is the common name for 1,2,3,4,5,6,7,8,8-nona-chloro-3a,4,7,7a-tetrahydro-4,7-methanoindan, and it is a member of the class of the cyclodiene pesticides (e.g., "technical chlordane") that were often used for management of subterranean termites (Isoptera). Chlordane mixtures (including alpha chlordane) were first produced in 1948, though commercial uses were later banned (1988) in the U.S.A. due to concerns about the risk of cancer (USEPA 2004).

Trans-nonachlor is the most bioaccumulative component of chlordane (USEPA 2004). Average concentrations of trans-nonachlor in silvery minnow carcasses (5±3 µg/kg wet weight) were similar to those found in fish sampled throughout the Rio Grande (Schmitt et al. 2004; 10±13 µg/kg wet weight), but generally less than those found in fish sampled nationwide (Schmitt et al. 1999; 39±102 µg/kg wet weight). No significant linear relationships was found between concentrations of trans-nonachlor in silvery minnows and their lipid content. An ANOVA test found significant differences in wet weight concentrations of trans-nonachlor ($F(2,9)=24.6$, $p<0.001$) in silvery minnows collected from the middle sites (Site 3 and Site 4) than in those collected from the upper sites (Table 5). Unless there are sources of trans-nonachlor (and many other organic chemicals) in the vicinity of Site 3 and Site 4, it is likely that bioaccumulation rate in fish at these sites was greater in this section of the river. Concentrations of trans-nonachlor in silvery minnows do not exceed levels of concern (Eisler 1990; Beckvar and Lotufo 2011).

PCBs

PCBs do not occur naturally in the environment. PCBs have been used as hydraulic lubricants, insulators, heat transfer fluids, dielectric fluid for transformers and capacitors, pesticide extenders, dust-reducing agents, flame retardants, sealants, and organic diluents (Hutzinger et al. 1974). PCBs accumulate from air, water, and in animals through the food web because they are highly lipid-soluble and persistent in the environment. PCBs were introduced in the U.S.A. in 1929 and certain uses were banned in 1979 (USEPA 1979). PCBs have been shown to adversely affect reproduction, thymic atrophy, enzyme induction, nervous systems dysfunction, behavioral abnormalities, liver injury, estrogenic activity, endocrine disruption, immune system suppression, deformities, hepatotoxicity, and tumor promotion in fish, wildlife, and experimental animals, and it is toxic to people (Eisler and Belisle 1996; Hoffman et al. 1996; Niimi 1996; ATSDR 2000; NMED 2009; Wenning et al. 2011).

Average total PCB concentrations in silvery minnows (15.3±10.1 µg/kg wet weight) were higher than average concentrations in channel catfish (*Ictalurus punctatus*) fillets (4.6±5.3 µg/kg wet weight), or in white bass (*Morone chrysops*) fillets from Cochiti Reservoir (Gonzales and Fresquez 2006), but less than average total PCB concentrations in whole body carp (90.7±13.0 µg/kg wet weight) or in white bass fillets (177 µg/kg wet weight) collected from the Rio Grande (NMED 2009, New Mexico Water Quality Control Commission 2010). Average concentrations of total PCBs in silvery minnows were in the low range of average total PCB concentrations reported in whole body cyprinids (range 18-320 µg/kg wet weight) collected across the U.S.A. (Stahl et al. 2009). Interestingly, the pattern and ratios of the different PCB congeners in silvery minnows were generally consistent between sites, but varied by sample year, suggesting PCB

congener patterns may vary by season, reflect atmospheric deposition patterns and sources, or reflect different rates of bioaccumulation, diet, or elimination processes in these fish.

Total PCB concentrations in whole fish associated with adverse effects (average 118, range 0.1 to 1502 µg/g wet weight) or with no effects (average 431, range 0.1 to 4668 µg/g wet weight) ranged widely and overlapped for marine and freshwater fish (USACE 2010; Wenning et al. 2011). No total PCB concentrations in silvery minnows were above the average concentration associated with adverse effect (118 µg/g wet weight). However, effect studies using total PCB concentrations ranged so widely as to make comparisons with concentrations in silvery minnows unsatisfactory. For example, toxicity studies for PCB-153 and PCB-180 with effects in common carp (*Cyprinus carpio*) were 0.04 µg/g wet weight and 0.06 µg/g wet weight, respectively, while the same two PCB congeners have higher effect concentrations for fathead minnow, ranging from 6,030,000 and 4,565,000 µg/g wet weight, respectively. Concentrations of PCB-153/163 and PCB-180/193 in silvery minnows were 1.4±0.9 µg/g wet weight and 1.3±0.9 µg/g wet weight, respectively, and therefore, exceed the effect studies involving carp but do not exceed the no effect studies involving fathead minnow.

During a review of the PCB toxicity thresholds for endangered fish, Meador (2000) derived a concentration associated with adverse effects at 2400 µg/kg dry weight on a per lipid basis. Average total PCB concentrations in silvery minnows (838±499 µg/kg dry weight on a per lipid basis) were below this threshold. Also, Olsson et al. (1999) reported skeletal deformities including craniofacial malformations associated with fish injected with 360 µg/kg PCB-190 wet weight on a per lipid basis. Silvery minnows had PCB-190 concentrations lower than 36 µg/kg wet weight on a per lipid basis. This suggests that PCB-induced deformity would be unlikely in the silvery minnows unless they were more sensitive than the zebrafish (*Danio rerio*) used by Olsson et al. (1999), therefore, PCB-90 is unlikely the cause of the deformed opercula commonly observed in silvery minnows (Davis and Lusk 2012). However, given the wide range of effect concentrations in fish, additional research could be conducted to determine if individual PCB congener concentrations in silvery minnows are associated with adverse sublethal effects.

Dioxins, Dibenzofurans, and TEQs

Certain PCB congeners are able to line up in a flat configuration and are considered "dioxin-like" as they may have a fraction of toxic equivalency (TEQ) to dioxin (i.e., 2,3,7,8-TCDD) (Wenning et al. 2011). Dioxins and dibenzofurans were not detected above the LOD in silvery minnows. Toxic equivalency factors (TEFs) from Van den Berg et al. (1998) were used for certain PCB congeners (PCB-105, PCB-118, PCB-156/157, and PCB-167) in silvery minnows to calculate TEQs. TEQs for silvery minnows ranged from 0.08 picograms TCDD per gram (pg /g) wet weight in silver minnows collected from Site 6 to 1.2 pg/g wet weight in fish collected from Site 3. TEQs in silvery minnows averaged 0.3±0.3 pg/g wet weight and averaged 4.3±4.1 pg/g wet weight on a per lipid basis. TEQs in silvery minnows were below those reported by Gonzales and Fresquez (2006) in fillets from fish collected from Abiquiu and Cochiti Reservoirs (range 3 to 300 pg/g wet weight), in fish collected from the Rio Grande (Schmitt et al. 2004; 1.8±1.2 pg/g), or in large bodied fish collected from the Rio Grande (NMED 2009; 2.1±0.9 pg/g wet weight). Steevens et al. (2005) proposed no effect and low effect tissue residue benchmarks from 57 to 700 pg /g wet weight on a lipid basis to protect early life stage fish. Concentrations in

silvery minnows would fall well below that range of potential effects in fish. Therefore, dioxin toxicity or its toxic equivalence using PCB congeners is not expected in silvery minnows at the tissue concentrations detected.

PBDEs

Total BDE in silvery minnows carcasses averaged 138±142 µg/kg wet weight and ranged from 11 µg/kg wet weight at Site 1 to 477 µg/kg wet weight at Site 4 (Table 5, Appendix 3E). On average, 76 percent of total BDE in silvery minnow carcasses was BDE-47, followed by BDE-100, BDE-154, BDE-49/71 and BDE-28, at 9, 3, 2.5 and 2 percent, respectively, similar to BDE congener patterns detected in other feral fish (Wenning et al. 2011). Patterns of the relative ratios of BDEs were similar in fish by site within a sample year than between sample years. For example, BDE-206 was not detected in silvery minnows collected in 2006, but was detected in silvery minnows collected during 2008 (Appendix 3E).

Little information is available, at present, on the toxicity of PBDEs in fish (Wenning et al. 2011). BDE-47 concentrations in whole fish associated with adverse effects (average 180, range 70 to 410 µg/g wet weight) or with no effects (average 140, range 3 to 410 µg/g wet weight) ranged widely and overlapped for freshwater fish (Chen et al. 2010, Chou et al. 2010, USACE 2010). BDE-47 in silvery minnow carcasses averaged 110±117 µg/kg wet weight and ranged from 6 µg/kg wet weight at Site 1 to 385 µg/kg wet weight at Site 4 (Appendix 3E, Table 5). None of the BDE-47 concentrations in silvery minnows were above the average concentration associated with adverse effect (180 µg/g wet weight). In a fathead minnow study, Muirhead et al. (2006) reported that egg laying in breeding pairs stopped after accumulation of BDE-47 in 10 days and cessation of spawning appeared to have occurred when peak body levels of 15 µg/g wet weight were reached in male fathead minnow. BDE-47 was not elevated above these thresholds of concern in silvery minnows. However, additional research on the effects of BDEs is warranted as there are few studies on the effects of PBDEs in fish. Marr et al. (2010) described research into the effects of BDE-47 on silvery minnows being conducted by the U.S. Geological Survey's Columbia Environmental Research Center.

CONCLUSIONS

Concentrations of inorganic contaminants in silvery minnows were similar to those in other fish species collected from the Rio Grande and were generally low, except for aluminum and zinc. Aluminum and zinc were moderately elevated in silvery minnows throughout the Middle Rio Grande, but were similar to concentrations in fish from other watersheds in New Mexico. Several elements, arsenic and barium, decreased in silvery minnows in a downstream manner, though concentrations of these elements in water or sediment did not also decrease downstream. Certain elements, including copper, lead, and nickel, were elevated in silvery minnows collected from the upper sites above levels of concern for these elements in laboratory studies involving sublethal effects. Research into the sublethal effects of aluminum, copper, lead, nickel, and zinc on silvery minnows is warranted.

Generally, organic contaminant concentrations in silvery minnows were low, except for PAHs. Certain PAHs, mostly naphthalenes, were moderately elevated in silvery minnows sampled throughout the Middle Rio Grande. One aliphatic hydrocarbon, n-undecane, common in fuels and diesel soot, was also elevated in silvery minnows collected at Site 1, the Rio Grande at Bernalillo, New Mexico. It was unclear why concentrations of several organochlorine pesticides, PCBs, and PBDEs, were elevated in silvery minnows collected from Site 3 and Site 4. Flame retardant chemicals, such as PBDEs used in furniture foam, were higher in silvery minnows than were total DDTs or total PCBs, but were below levels of concern compared with laboratory studies. Research into the sublethal effects of PAHs on silvery minnows is warranted.

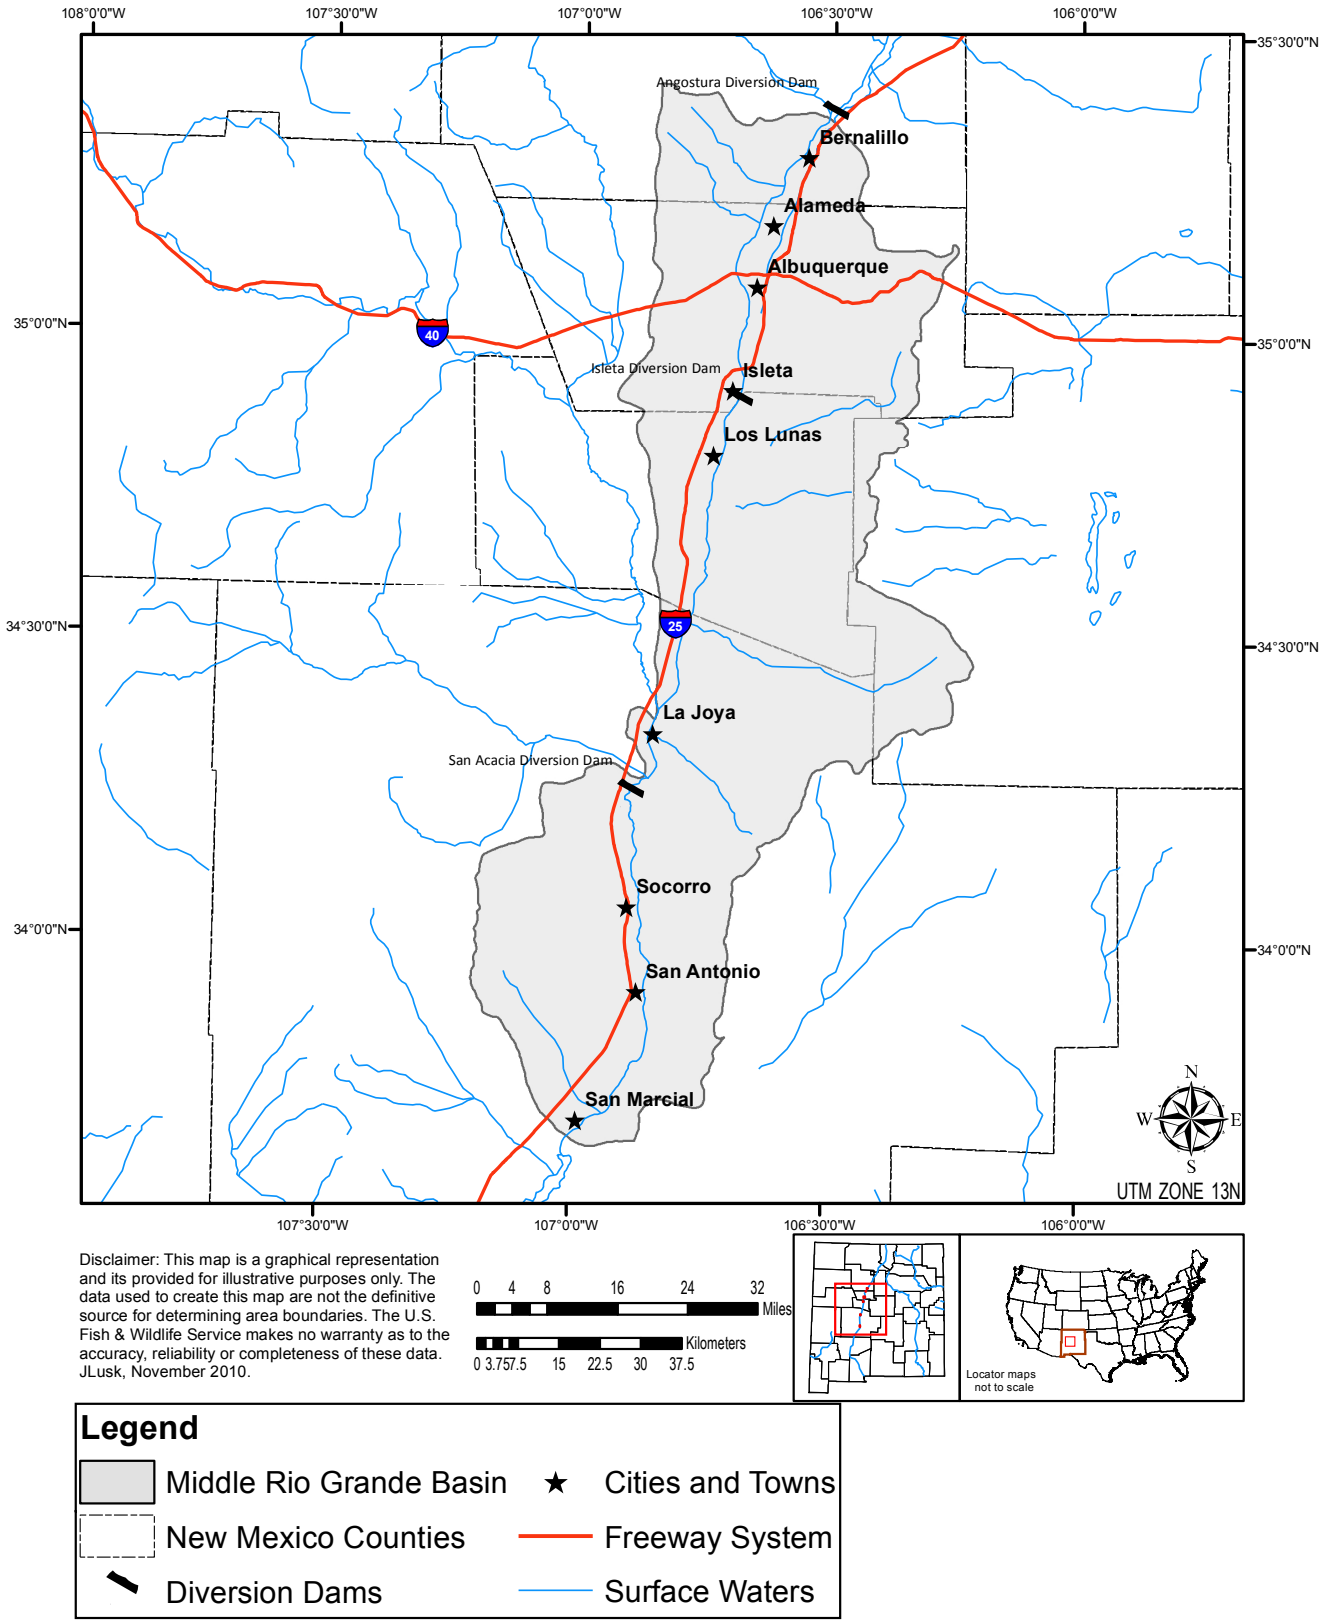

Figure 1. Location of the Middle Rio Grande Watershed and RGSM Health Study Area in New Mexico.

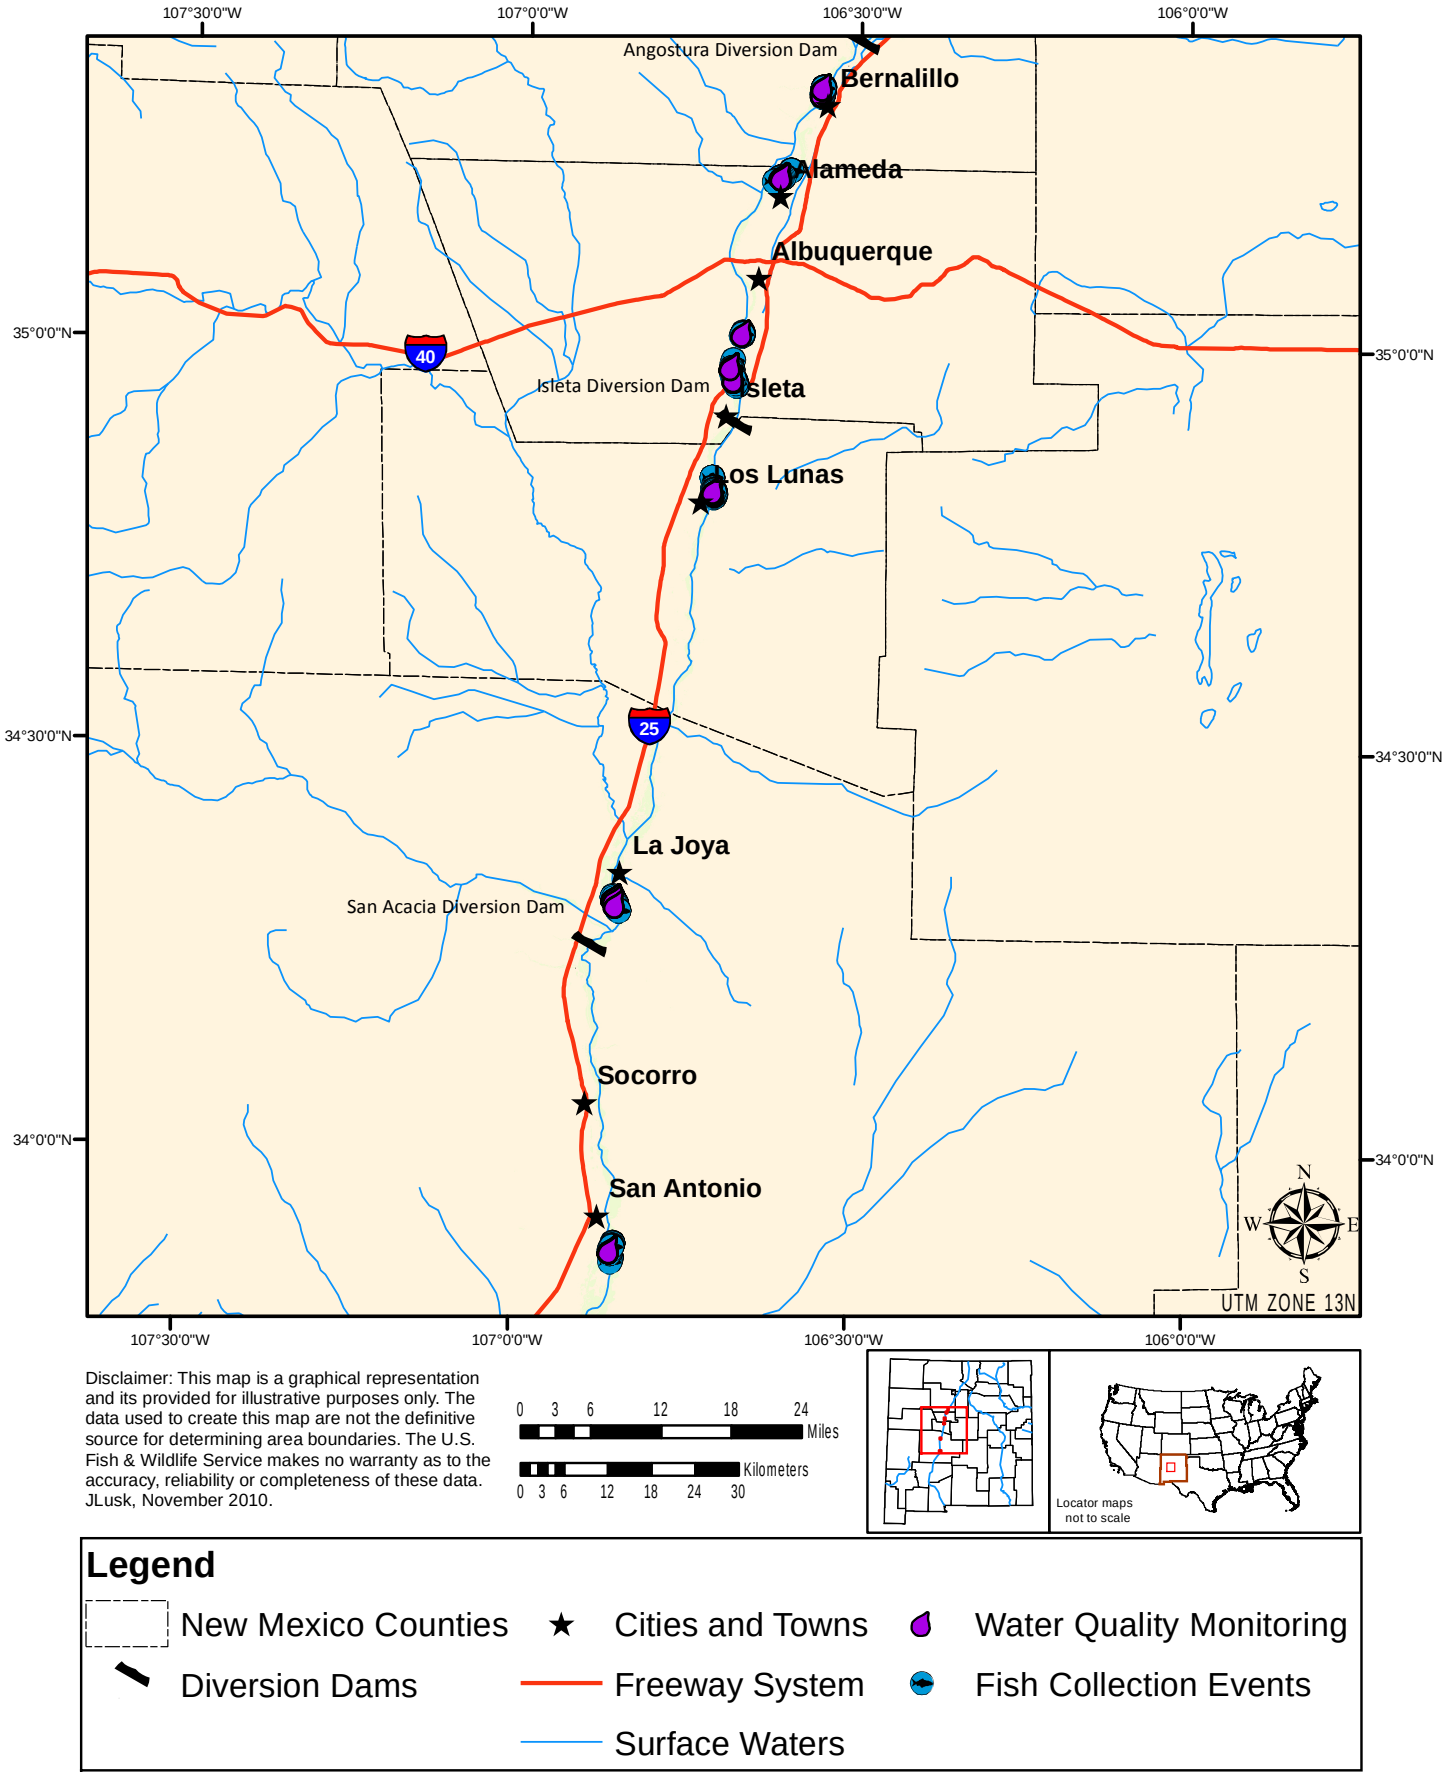

Figure 2. Location of the Six RGSM Health Study Sites along the Middle Rio Grande in New Mexico.

Table 1. Site number, site name name, latitude and longitude (in decimal degress) of a central point, and description of the RGSM Health Study sampling sites.

Site Number	Site Name	Latitude and Longitude (central point - decimal degrees)	Site Location Description
1	Rio Grande at Bernalillo, New Mexico	35.3181, -106.5589	approximately 0.1 mi upstream to 0.8 mi downstream of the Highway 550 Bridge crossing
2	Rio Grande at Alameda, New Mexico	35.2101, -106.6172	approximately 0.7 mi upstream and 1.1 mi downstream of AMAFCA North Diversion Channel mouth
3	Rio Grande at Los Padillas, New Mexico	34.9716, -106.6897	Just north of the Interstate 25 Bridge to approximately 5 mi upstream
4	Rio Grande at Los Lunas, New Mexico	34.8228, -106.7149	approximately 0.6 mi to 2.4 mi north of the Main Street (Highway 6) Bridge crossing
5	Rio Grande at La Joya, New Mexico	34.3073, -106.8493	approximately 2.4 mi to 3.8 mi north of the confluence with the Rio Salado
6	Rio Grande near San Antonio, New Mexico	33.8775, -106.8495	approximately 0.5 mi downstream and 1.2 mi upstream of Bosque del Apache National Wildlife Refuge (BdANWR) North Boundary

Table 2. Chemical names, abbreviations, analytical methods, limit of detection. ["<", less than; "NA", not available]

Chemical Grouping	Analytical Method[1]	Limit of Detection[2]	Chemical Name or Abbreviation[3]	CAS[4] Number	Alternative Chemical Name
Aromatic hydrocarbon	GCMS	<0.45	1,6,7-trimethylnaphthalene	2131386	1,6,7-trimethylnaphthalene
Aromatic hydrocarbon	GCMS	<0.20	1-methylnaphthalene	90120	1-methylnaphthalene
Aromatic hydrocarbon	GCMS	<0.51	1-methylphenanthrene	832699	1-methylphenanthrene
Aromatic hydrocarbon	GCMS	<0.64	2,6-dimethylnaphthalene	28804888	2,6-dimethylnaphthalene
Aromatic hydrocarbon	GCMS	<0.20	2-methylnaphthalene	91576	2-methylnaphthalene
Aromatic hydrocarbon	GCMS	<0.24	acenaphthalene	208968	acenaphthalene

Table 2. Chemical names, abbreviations, analytical methods, limit of detection. ["<", less than; "NA", not available]

1-Tissue processing and analytical methods are fully described in Appendices 3A and 3B. Analytical method identifiers: GCMS, gas chromatography, mass spectroscopy; ICP-AES, inductively coupled plasma mass spectroscopy; AFS, atomic fluorescence; GC-ECP, gas chromatography, electron capture detection; ICP-MS, inductively coupled plasma mass spectroscopy; CVAAS, cold-vapor atomic absorption spectroscopy.

2-Liimit of detection reported is the lowest method detection limit for the sample batch.

3-Chemical name used in this report. PCB and BDE congeners are designated using the Ballschmiter-Zell numbering system. Certain PCB or BDE congeners will co-elute during analysis.

4-Chemical Abstract Service (CAS) number. "NA" indicates that no CAS number is available at the time of this report.

Table 3. Moisture content, methyl mercury and element concentrations in Rio Grande silvery minnow carcasses collected from six sites (Table 1; Figure 2) along the Middle Rio Grande, New Mexico, during 2006-2008, and all site data combined.

[Moisture content, methyl mercury and element concentration data are the mean±1 standard deviation with the number of fish composite samples and range of concentrations in parentheses. Means within a row that have no upper case letters are not significantly different. Means within a row with upper case letters and sharing the same upper case letter are not significantly ($P<0.05$) different. "±", plus or minus; "MRG", Middle Rio Grande; "NM", New Mexico; Site 1, MRG at Bernalillo, NM; Site 2, MRG at Alameda, NM; Site 3, MRG at Los Padillas, NM; Site 4, MRG at Los Lunas, NM; Site 5, MRG at La Joya, NM; Site 6, MRG near San Antonio, NM; "µg/g", microgram per gram; dry, dry weight basis; wet, wet weight basis; "<", less than; "%", percent]

Table 5. Carcass concentrations of organic chemicals and lipid content in Rio Grande silvery minnow collected from 6 sites along the Middle Rio Grande, New Mexico, during 2006-2008, (Table 1, Figure 1) and grouped into river sections including the Upper Sites, Middle Sites, and Lower Sites, as well as all data combined.

[Organic chemical concentration data are mean ± 1 standard deviation with the number of fish composite samples and range of concentrations in parenthesis. Means within a row that have no upper case letters are not significantly different. Means within a row with upper case letters and sharing the same upper case letter are not significantly (P<0.05) different. "±", plus or minus; "MRG", Middle Rio Grande; "NM", New Mexico; Site 1. MRG at Bernalillo, NM; Site 2. MRG at Alameda, NM; Site 3. MRG at Los Padillas, NM; Site 4. MRG at Los Lunas, NM; Site 5. MRG at La Joya, NM; Site 6. MRG near San Antonio, NM; µg/kg, microgram per kilogram; wet weight; <, less than]

Organic Chemical (µg/kg wet weight)	Upper Sites (Site 1 & Site 2 combined)	Middle Sites (Site 3 & Site 4 combined)	Lower Sites (Site 5 & Site 6 combined)	All Sites Combined

1. ECDMS Analytical Results Report 5/27/2010

Catalog Number	Purchase Order Number	Lab ID	Catalog Submitter	ECDMS User ID
2020128	94420-09-Y004	TERL	Lusk, Joel - Albuquerque, NM	r2alfo

Catalog Title	Rio Grande Silvery Minnow Health Study
Lab Name:	Trace Element Research Laboratory

Notes, Symbols and Abbreviations Used
Based on the report options selected the report should be **printed in landscape mode**
Notes, Symbols and Abbreviations Used The following may appear before a reported result (e.g. < 1234). < - Less than symbol indicates that the actual result is less than the reported detection limit. > - Greater than symbol indicates that the actual result is greater than the reported result.
All results are reported as 3 significant digits.
All results are reported as parts per million (ppm), or percent, unless otherwise noted.

1. Integrity Report

Lab Receipt Date	10/01/2009	Lab Approval Date	10/01/2009

Catalog Problems
No problems reported
Problem Resolution

2. Bulk Data

	Methyl Mercury	Partial Carcass	Dry	1.55	1.33	4.32	85.5

*** For a spike to be a valid measure of method accuracy, this ratio must be higher than 1.0.

10. QAQC Summary

1. Procedural Blank Summary

Procedural Blank Summary of Blank Equivalent Concentration (BEC) Data

Within a lab sample matrix, there must be three or more Blank results for a given analyte in order to generate a report.

Analyte	Lab Sample Matrix	No. of Records	Basis	Lowest BEC (ppm)	Highest BEC (ppm)	BEC Mean (ppm)	BEC STDEV
Mercury	Animal Tissue	4	Dry	< 0.00430	< 0.00704	0.00280	0.000640

BEC = Blank Equivalent Concentration   STD = Standard Deviation

10.2. Duplicate Summary

Duplicate Summary of Relative Percent Difference (RPD) Data

Within a lab sample matrix and concentration range, there must be three or more Duplicate results for a given analyte in order to generate a report.

Mean concentration greater than 10 times the Limit of Detection						
Analyte	**Lab Sample Matrix**	**No. of Samples**	**Lowest RPD**	**Highest RPD**	**RPD Mean (ppm)**	**RPD STD**
Mercury	Animal Tissue	4	0.73	3.8	2.16	1.27

RPD = Relative Percent Difference STD = Standard Deviation

10.3. Spike Summary

Spike Summary of Percent Recovery (PR) Data

Within a lab sample matrix, there must be three or more Spike results for a given analyte in order to generate a report.

Analyte	Lab Sample Matrix	No. of Samples	Lowest PR	Highest PR	PR Mean	PR STD
Mercury	Animal Tissue	4	87.34	105.09	99.83	8.36

PR = Percent Recovery STD = Standard Deviation

10.4. SRM Summary

Standard Reference Material Summary of Percent Recovery (PR) Data

Within an SRM ID, there must be three or more Recoveries for a given analyte in order to generate a report.

SRM ID: NRCC DOLT-3 SRM Name: Dogfish Liver					
Analyte	**No. of Records**	**Lowest PR**	**Highest PR**	**PR Mean**	**PR STDEV**
Mercury	4	102.37	107.42	105.71	2.26

SRM ID: NRCC DORM-2 SRM Name: Dogfish Muscle					
Analyte	**No. of Records**	**Lowest PR**	**Highest PR**	**PR Mean**	**PR STDEV**
Mercury	4	93.32	104.31	97.58	4.87

PR = Percent Recovery STD = Standard Deviation

11. QA/QC Anomalies

1. Blank Frequency Anomalies

The required number of blank analyses were performed.

11.2. Duplicate Frequency Anomalies

The required number of duplicate analyses were performed.

11.3. Spike Frequency Anomalies

The required number of spike analyses were performed.

11.4. Reference Material Frequency Anomalies

The required number of Standard Reference Material analyses were performed.

11.5. Mass Spec Frequency Anomalies

No Carbamate, OC, or OP data exists in this set of results; therefore, the anomaly test was not performed.

11.6. Limit of Detection Anomalies

Limits of Detection were within the contract requirements.

11.7. Blank Anomalies

Procedural Blank analyses were acceptable.

11.8. Duplicate Anomalies

All duplicate results were within normal limits.

11.9. Spike Anomalies

All spike results were within normal limits.

11.10. S.R.M. Anomalies

All SRM results were within normal limits with the following exceptions.

Analyte	S.R.M. ID	Certified Value	95% Confidence Interval	LOD (ppm/%)	Result (ppm/%)	% Recovery	See QA/QC Note No.
Manganese	NIST 2976	33.0	2.00	0.207	38.6	117	1
Strontium	NIST 2976	93.0	2.00	0.0459	65.2	70.1	2

S.R.M Names

SRM ID	SRM Name
NIST 2976	Mussel Tissue

11.11. QA/QC Notes

QA/QC Note Number and Comments
Sample IDs 7-08-2, 7-08-3, 7-08-5 and 7-08-6 had ratios of greater than 1 for MeHg:Hg in the data report. To express MeHg as Hg you have to divide the MeHg based values by approx. 1.075. In doing this, the ratio values for all samples that were analyzed for MeHg and Hg are acceptable. 1-2 The values are acceptable for Mn and Sr in SRM Nist 2976 and should have no effect on the interpretation of the data. QA/QC Approved: Brenda Montgomery, Inorganic Analytical Chemist

12. Analytical Methods

Below are the analytical methods used by TERL to produce the results included in this report.

Method Codes:	001 005

Lab Matrix	Analyte
Animal Tissue	Aluminum
	Boron
	Barium
	Beryllium
	Chromium
	Copper
	Iron
	Magnesium
	Manganese
	Molybdenum
	Nickel
	Strontium
	Vanadium
	Zinc

Method Code: 001

LABORATORY: Trace Element Research Laboratory

Digestion of biological tissue.

Liquid or solid biological tissue samples are wet digested with nitric acid and converted into acidic digest solutions for analysis by various atomic spectroscopy methods. When possible, tissue is freeze dried in order to minimize loss of analytes and to facilitate subsequent sample preparation steps, and then homogenized to a fine powder by ball-milling in plastic containers. Approximately 0.20 to 0.25 g of powdered tissue is weighed into a Teflon reaction vessel and 3 ml of HNO3 are added. The closed reaction vessel is heated in a 130 C oven until digestion is complete. Samples are then diluted to a final volume of 20 ml with quartz distilled water and stored in 1 oz. polyethylene bottles for later analysis by instrumental techniques.

Method Code: 005

LABORATORY: Trace Element Research Laboratory

Analysis of trace metals by inductively coupled plasma
optical emission spectroscopy (ICP).

Liquid samples are nebulized and the resulting aerosol is transported to the plasma torch. Element-specific atomic-line emission spectra are produced by a inductively coupled argon plasma. The spectra are dispersed by a grating spectrometer, and the intensities of the lines are monitored by photomultiplier tubes or solid state detectors. Samples are quantitated by comparison with external standards. One or more internal standards may be incorporated to compensate for physical effects resulting from viscosity and varying levels of total dissolved solids in the samples. Background correction is required and is measured adjacent to analyte lines on samples during analysis.

Method Codes:	001 016

Lab Matrix	**Analyte**
Animal Tissue	Arsenic

Method Code: 016

LABORATORY: Trace Element Research Laboratory

Analysis of trace metals in water samples by inductively
coupled plasma-mass spectroscopy (ICP-MS).

Concentrations of trace elements in water samples are determined with an atomic spectroscopy method that relies on ionization of sample constituents in a high temperature argon plasma and separation of positively-charged ions on the basis of their

mass:charge ratios (m:z) by a quadrupole mass spectrometer. The method offers extremely low detection limits but is subject to interferences from atomic and molecular ions having values within 1 AMU of the target ions. Sample preconcentration and matrix elimination can sometimes eliminate these problems, along with those resulting from high total dissolved solids.

Method Codes:	003 007

Lab Matrix	Analyte
Water	Mercury

Method Code: 003

LABORATORY: Trace Element Research Laboratory

Digestion of water, soil, sediment, and biological tissue
for mercury analysis.

Before samples are analyzed by the CVAAS method in use in this laboratory, the mercury is converted to the Hg2+ form. Mercury is digested by a modified version of EPA method 245.5 and 245.6. Sediment and tissue samples can be analyzed either freeze dried or on a wet basis. Sediment samples are homogenized by mixing before subsampling, while tissue samples are homogenized in the original sample containers either after freeze drying or with a Tekmar Tissumizer and subsampled. Samples are digested with nitric acid, sulfuric acid, potassium permanganate, and potassium persulfate in polypropylene tubes in a water bath at 90-95 C. Before analysis, hydroxylamine hydrochloride is added to reduce excess permanganate and the samples are brought to volume with distilled-deionized water.

Method Code: 007

LABORATORY: Trace Element Research Laboratory

Analysis of mercury by cold-vapor atomic absorption
spectroscopy (CVAAS).

In this procedure, divalent mercury (Hg++) in aqueous samples (digests of water, tissue or sediment samples) is reduced to the elemental state (Hgo) by a strong reducing agent (stannous chloride). Gaseous Hgo enters the sweep gas and is introduced into an atomic absorption cell, where light produced by a mercury vapor lamp is absorbed by the free Hg atoms. Mercury in the sample is determined by comparing light absorption of the sample with that of external calibration standards.

Method Code: 004

LABORATORY: Trace Element Research Laboratory

Digestion of water samples for "total recoverable" metals
(other than mercury).

Water samples are digested for two hours at 85 degrees Centigrade in polyethylene containers with ultrapure nitric and hydrochloric acids. Acid strength, on a vol:vol basis, is 1% HCl and 0.5% HNO3. Sample aliquots for digestion are taken after vigorous shaking to assure resuspension of solids that may have settled. The original sample must have had preservative added (usually HNO3) in order to ensure that metals do not adhere to the walls of the container.

The method offers extremely low detection limits but is subject to interferences from atomic and molecular ions having values within 1 AMU of the target ions. Sample preconcentration and matrix elimination can sometimes eliminate these problems, along with those resulting from high total dissolved solids.

Method Codes:	014

Lab Matrix	Analyte
Animal Tissue	% Moisture

Method Code: 014
LABORATORY: Trace Element Research Laboratory Moisture content of sediment, soil, and tissue samples. Moisture content is determined by weight loss upon freeze-drying, and is expressed as weight percent of the original wet sample. Depending upon sample size, either the whole sample or a representative aliquot is frozen and then dried under vacuum until a constant weight is attained. Samples are prepared and dried using plastic materials, whenever possible, in order to minimize potential contamination artifacts that might impact subsequent trace element analysis.

Method Codes:	024

Lab Matrix	Analyte
Animal Tissue	Mercury

Method Code: 024
LABORATORY: Trace Element Research Laboratory Determination of mercury in tissue and sediment Determination of mercury in tissue and sediment samples by decomposition, trapping, and atomic absorption. Total mercury is determined in wet or dry samples by combustion in a stream of oxygen, trapping on a gold column, release by electrothermal heating, and analysis by atomic absorption. Mercury is reported in ppm on either a wet or dry weight basis.

Method Codes:	026

Lab Matrix	Analyte
Animal Tissue	Methyl Mercury

Method Code: 026
LABORATORY:Trace Element Research Laboratory Determination of methyl mercury in water Determination of methyl mercury in water by distillation, ethylation, trapping, gas chromatography, and atomic fluorescence. Methyl mercury in water is distilled to separate it from interfering species and then ethylated with sodium tetraethyl borate. Methyl ethyl mercury is trapped on a Tenax column and then separated on an isothermal GC column. Following pyrolysis of the separated species, Hg is detected by atomic fluorescence.

Code List

If appropriate, labs are instructed to use the following codes when entering laboratory notes. The labs may use one or more of the codes in each note displayed above.

Code	Comment
A	Values reported based on Aldrin response factor.
C	Sample possibly compromised due to improper handling / packaging.
D	Sample was deleted from the catalog by the submitter.
H	Due to sample characteristics it was difficult to obtain adequate sample homogeneity - precision was impacted.
I	Interferences occurred during analysis.
L	Sample compromised or destroyed during shipment - sample not analyzed.
M	Compound identity was confirmed by GC/MS.
N	Sample was not analyzed.
P	Sample destroyed during preparation at lab - sample not analyzed.
Q	Insufficient sample quantity to perform requested analysis.
R	Sample is highly decomposed - results may be impacted.
S	Sample was substituted by the submitter.
T	Retention time relative to Aldrin.
U	GC/MS identifies the unknown compound to be _____ (fill in analyte).
W	Insufficient sample quantity to perform duplicate / spike analyses.
Y	Sample was analyzed but results may be impacted (see 'C')

10. QAQC Summary

1. Procedural Blank Summary

Procedural Blank Summary of Blank Equivalent Concentration (BEC) Data

Within a lab sample matrix, there must be three or more Blank results for a given analyte in order to generate a report.

10.2. Duplicate Summary

Duplicate Summary of Relative Percent Difference (RPD) Data

Within a lab sample matrix and concentration range, there must be three or more Duplicate results for a given analyte in order to generate a report.

10.3. Spike Summary

Spike Summary of Percent Recovery (PR) Data

Within a lab sample matrix, there must be three or more Spike results for a given analyte in order to generate a report.

10.4. SRM Summary

Standard Reference Material Summary of Percent Recovery (PR) Data

Within an SRM ID, there must be three or more Recoveries for a given analyte in order to generate a report.

11. QA/QC Anomalies

1. Blank Frequency Anomalies

The required number of blank sample analyses were performed with the following exceptions.				
Analyte	**Number of Samples**	**Number of Blanks**	**Frequency (%)**	**See QA/QC Note No.**
PCB-1242	13	0	0	1
PCB-1248	13	0	0	2
PCB-1254	13	0	0	3
PCB-1260	13	0	0	4

11.2. Duplicate Frequency Anomalies

The required number of duplicate sample analyses were performed with the following exceptions.					
Analyte	**Lab Matrix**	**Number of Samples**	**Number of Duplicates**	**Frequency (%)**	**See QA/QC Note No.**
1,2,3,4,6,7,8-HpCDD	Animal Tissue	8	0	0	5
1,2,3,4,6,7,8-HpCDF	Animal Tissue	8	0	0	6

11.10. S.R.M. Anomalies

No SRM data exists in this set of results; therefore, the anomaly test was not performed.

11.11. QA/QC Notes

QA/QC Note Number and Comments
Additional TDI Comments: 06385810 (Water) Insufficient sample for analysis. per Juan. ACF Comments: 1-4 Other PCB blank analyses were performed. This is acceptable. 5-371 A blank spike duplicate analyses was performed. This is acceptable. 372-790 A Blank spike analyses was performed. This is acceptable 791 Analyte detectable levels were to low for mass spec confirmation. 792-810 These LODs were higher than the ECDMS default. They are acceptable. 811-814 These analytes were reported present in the blank. Results that are less than ten times the amount found in the blank are considered non-detects. 815-817 The spike recoveries for these analytes were low. Results may be Biased low. QA/QC reviewed 04/06/2010 Walter Riley

12. Analytical Methods

Below are the analytical methods used by TDI to produce the results included in this report.

Method Codes:	001

Lab Matrix	Analyte
Animal Tissue	% Lipid
	% Moisture

Method Code: 001

LABORATORY: TDI Brooks International, Inc.

Tissue Extraction Method (PAH and OCs)

Tissue samples are either immediately processed or stored frozen (-20°C) until processing. Tissues are processed as appropriate for the tissue type (e.g. dissection, shucking). Processed tissues are homogenized using a variety of mechanical methods (Waring blender, Hobart meat grinder or Tissumisser), depending upon the tissue amount and type. After homogenization, an approximate 1 g aliquot is removed and dried in an oven at 105°C to a constant weight to determine % moisture. The remaining samples are stored in certified pre-cleaned jars frozen (- 20°C) until analysis. Prior to extraction, tissue samples may be lypholized or a wet aliquot is chemically dried using a dessicant such as Hydromatrix or sodium sulfate. Samples are then extracted using a Dionex ASE200 Accelerated Solvent Extractor (ASE). The dried sample or the sample and dessicant material is loaded into 22 or 33 mL stainless steel ASE extraction tubes. The extraction are performed using 100% dicholormethane at 100°C and 2000 psi. The extracted organics dissolved in the solvent are collected in 60 mL glass vials. The extract is concentrated to approximately 10 mL in the collection vials and then transferred to 25 mL Kurdena-Danish (KD) concentrator tubes. The sample extract is concentrated to 3 mL in a water bath at 55-60°C. If lipid weight is required, a 100 mL aliquot is removed and weighed using a microbalance. Interfering non-contaminant organic material (primarily lipids) must be removed prior to instrument analyses.

The extract is processed through silica gel/alumina chromatography columns and High Performance Liquid Chromatography (HPLC). The remaining 2.9 mL of sample extracted are loaded on top of 300 mm x 19 mm glass liquid chromatography columns packed with 10 g of deactivated alumina and 20 g of deactivated silica gel. The columns are loaded in 100 % dichloromethane. The dichloromethane is replaced by adding 40 mL of pentane. The extract is carefully added to the top of the chromatography columns. The column is flushed at a rate of 1-2 mL per minute using 200 mL of 50:50 pentane/dichloromethane and collected into 250 mL flasks. The eluent collected in the 250 mL flask is evaporated to 2 mL using a waterbath at 55-50°C. The samples is transferred into 4 mL amber vials. Extracts subsequently processed by HPLC to further remove lipid interferences. Lipid removal is accomplished by flushing samples with dichlormethane through size exclusion Phenogel 10 m GPC 100 A columns. Approximately 40 mL is collected using a fraction collector, which is concentrated to 0.5 mL using a water bath at 55-60C. The concentrated extract is then analyzed by GC/MS for polynuclear aromatic hydrocarbons (PAHs) or GC/ECD for selected organochlorines (OCs).

Additional column chromatography is required to separate PCBs from toxaphene/pesticides when toxphene analysis is required and to separate planar PCBs. If toxaphene analyses is required, an aliquot of the extract prior to HPLC clean up is processed through a 3% deactivated silica gel column. The column is packed in dicloromethane which is then flushed with 50 mL of pentane. The sample extract is transferred to the top of the column and flushed with 100 mL of pentane. The fraction contains PCBs and DDTs. The column is then flushed with 120 mL of 50:50 pentane/dichloromethane. This fraction contains toxaphene and chlorinated pesticides. Both fractions are reduced to 1 mL using a water bath at 55-60°C. The extracts are then ready for instrument analysis.

If planar PCB analyses are required, the PCB/DDT fraction prepared by 3% silica gel column is further processed by column chromatography packed with 2 g of 1:19 (5% by weight) mixture of activated carbon/Celite. The column and flushed with 25 mL of 1:4 dichloromethane/cyclohexane mixture. The sample is added to the top of the column and flushed with 50 mL of 1:4 dichloromethane/cyclohexane mixture, followed by 30 mL of 9:1 dichloromethane/toluene. This is followed by the addition of 40 mL of toluene. The toluene fraction contains the planar PCBs and is concentrated to 1 mL in a Zymark TurboVap II concentrator at 42°C and 20 psi. The sample is ready for instrument analysis.

LABORATORY: TDI Brooks International, Inc.

Aromatic Hydrocarbon Determination by Selected Ion Monitoring (SIM) Gas Chromatography/ Mass Spectrometry (GC/MS)

Polycyclic aromatic hydrocarbons (PAH) and their alkylated homologues are analyzed in sample extracts by a HewlettPackard, model 5890 GS and model 5972 MS operated in SIM using a capillary column. The GC is operated in splitless mode and the capillary column is an Agilent Technologies HP-5MS (60 m x 0.25 mm ID and 0.25 mm film thickness). The carrier gas is helium at

a flow rate of 1 mL/minute. The temperature of the injection port is 300°C and transfer line is 290°C. The initial oven temperature is 60°C, the ramp rate is 7°C/minutes to a final oven temperature of 310°C and held for 20 minutes. For analyte identification, the extracted ion current profiles of the primary m/z and the confirmatory ion for each analyte must be at a maximum in the same scan or within one scan of each other and the retention time must fall with 5 seconds of the retention time of the authentic standard or alkyl homologue grouping. The pattern of alkylated PAH homologue groupings is established by analysis of reference oil standards. The relative peak heights of the primary mass ion compared to the confirmation or secondary mass ion must fall within 30 % of the relative intensities of these masses in a reference mass spectrum.

Chlorinated Hydrocarbon Determination by Gas Chromatography/Electron Capture Detection (GC/ECD)

Chlorinated hydrocarbons are determined in samples by GC/ECD. Samples are extracted as previously described and analyzed on a HewletPackard (HP), model 5890 GC equipped with an ECD. Between 1 to 5 mL of sample is injected using an HP, model 7673A autosampler. The instrument is set up with dual columns. The primary capillary column is a J&W DB-5 (30 m x 24 mm ID and 0.25 mm film thickness). The second column, a confirmation column, is a J&W DB-17HT (30 m x 0.25 mm ID and 0.15 mm film thickness). The inlet system is splitless and the carrier gas is helium at a flow rate of 1 mL/min. For the analysis of standard halogenated hydrocarbons, the temperature of the injection port is 275°C and the detector is 325°C. The initial oven temperature is 100°C with a hold time of 1 minute. The ramp rate is 5°C/minute to 140°C with a hold time of 1 minute, followed by a ramp rate of 1.5°C /minute to 250C with a hold time of 1 minute and finally a ramp rate of 10°C/minutes to 300°C with a final hold time of 5 minutes. For planar PCBs the instrument is operated in the splitless mode with helium as the carrier gas with a flow rate of 1 mL/minute. The temperature of the injection port is 275°C and the detector is 325°C. The initial oven temperature is 100°C, which is held for 1 minute. The ramp rate is 10°C/minute to 150°C, followed by a ramp rate of 6.0°C/minute to 270°C with a hold time of 3 minutes. The retention time of sample analytes must fall within 15 seconds of the retention time of analytes in a calibration standard or a retention index solutions. The levels of aroclors and toxophene are determined using retention index solutions of both complex mixtures. Arochlors are determined in a similar method to that described in EPA SW-846 Test Methods for Evaluating Solid Waste Physical/Chemical Methods, Method 8082 (1997).

LABORATORY: TDI Brooks International, Inc. Tissue Extraction Method (PAH and OCs)

Tissue samples are either immediately processed or stored frozen (-20°C) until processing. Tissues are processed as appropriate for the tissue type (e.g. dissection, shucking). Processed tissues are homogenized using a variety of mechanical methods (Waring blender, Hobart meat grinder or Tissumisser), depending upon the tissue amount and type. After homogenization, an approximate 1 g aliquot is removed and dried in an oven at 105°C to a constant weight to determine % moisture. The remaining samples are stored in certified pre-cleaned jars frozen (- 20°C) until analysis. Prior to extraction, tissue samples may be lypholized or a wet aliquot is chemically dried using a dessicant such as Hydromatrix or sodium sulfate. Samples are then extracted using a Dionex ASE200 Accelerated Solvent Extractor (ASE). The dried sample or the sample and dessicant material is loaded into 22 or 33 mL stainless steel ASE extraction tubes. The extraction are performed using 100% dicholormethane at 100°C and 2000 psi. The extracted organics dissolved in the solvent are collected in 60 mL glass vials. The extract is concentrated to approximately 10 mL in the collection vials and then transferred to 25 mL Kurdena-Danish (KD) concentrator tubes. The sample extract is concentrated to 3 mL in a water bath at 55-60°C. If lipid weight is required, a 100 mL aliquot is removed and weighed using a microbalance. Interfering non-contaminant organic material (primarily lipids) must be removed prior to instrument analyses.

The extract is processed through silica gel/alumina chromatography columns and High Performance Liquid Chromatography (HPLC). The remaining 2.9 mL of sample extracted are loaded on top of 300 mm x 19 mm glass liquid chromatography columns packed with 10 g of deactivated alumina and 20 g of deactivated silica gel. The columns are loaded in 100 % dichloromethane. The dichloromethane is replaced by adding 40 mL of pentane. The extract is carefully added to the top of the chromatography columns. The column is flushed at a rate of 1-2 mL per minute using 200 mL of 50:50 pentane/dichloromethane and collected into 250 mL flasks. The eluent collected in the 250 mL flask is evaporated to 2 mL using a waterbath at 55-50°C. The samples is transferred into 4 mL amber vials. Extracts subsequently processed by HPLC to further remove lipid interferences. Lipid removal is accomplished by flushing samples with dichlormethane through size exclusion Phenogel 10 m GPC 100 A columns. Approximately 40 mL is collected using a fraction collector, which is concentrated to 0.5 mL using a water bath at 55-60C. The concentrated extract is then analyzed by GC/MS for polynuclear aromatic hydrocarbons (PAHs) or GC/ECD for selected organochlorines (OCs).

Additional column chromatography is required to separate PCBs from toxaphene/pesticides when toxphene analysis is required and to separate planar PCBs. If toxaphene analyses is required, an aliquot of the extract prior to HPLC clean up is processed through a 3% deactivated silica gel column. The column is packed in dicloromethane which is then flushed with 50 mL of pentane. The sample extract is transferred to the top of the column and flushed with 100 mL of pentane. The fraction contains PCBs and DDTs. The column is then flushed with 120 mL of 50:50 pentane/dichloromethane. This fraction contains toxaphene and chlorinated pesticides. Both fractions are reduced to 1 mL using a water bath at 55-60°C. The extracts are then ready for instrument analysis.

If planar PCB analyses are required, the PCB/DDT fraction prepared by 3% silica gel column is further processed by column chromatography packed with 2 g of 1:19 (5% by weight) mixture of activated carbon/Celite. The column and flushed with 25 mL of 1:4 dichloromethane/cyclohexane mixture. The sample is added to the top of the column and flushed with 50 mL of 1:4 dichloromethane/cyclohexane mixture, followed by 30 mL of 9:1 dichloromethane/toluene. This is followed by the addition of 40 mL of toluene. The toluene fraction contains the planar PCBs and is concentrated to 1 mL in a Zymark TurboVap II concentrator at 42°C and 20 psi. The sample is ready for instrument analysis.

Determination of Aliphatic Hydrocarbons in Soil/Sediment

Sediment samples are extracted as described in method 005. Aliphatic hydrocarbons are determined by quantifying target analytes with a gas chromatography/flame ionization detection (GC/FID)

Aliphatic hydrocarbons are analyzed using a HewelettPackard, model 5890 Gas Chromatograph (GC) with a Flame Ionization Detector (FID) operated in a splitless mode. A HP-1MS capillary column (30m x 0.25 mm ID and 0.25 mm film thickness) is used to resolve peaks. The carrier gas is helium at a flow rate of 1.5 mL/min. The temperature of the injection port is 300°C and transfer line is 300C. The initial oven temperature is 60°C, the ramp rate is 12°C/min to a final oven temperature of 180°C. Normal alkanes with 10 to 34 carbons and the isoprenoids pristine and phytane are determined using this procedure. For analytes of interest, a response factor relative to the internal standard is determined at each calibration level. All 5 response factors are averaged for a mean relative response factor. Data are surrogate corrected.

Polybrominated Diphenyl Ether (PBDE) Determination by Negative Chemical Ionization (NCI)-Selected Ion Monitoring (SIM) Gas Chromatography/Mass Spectrometry (GC/MS)

Polybrominated diphenyl ethers are analyzed in sample extracts by a Thermo Trace GC and DSQ-II MS operated in SIM using a capillary column. The GC is operated in splitless mode using a PTV injection port and the capillary column is an Agilent Technologies DB-XLB (15 m x 0.25 mm ID and 0.10 mm film thickness). The carrier gas is helium at a flow rate of 1 mL/minute and methane is used as the reactant gas with a flow rate of 2.0 mL/min. The temperature of the injection port is 40 degrees C (ramp to 300 degrees C) and transfer line is 290 degrees C. The initial oven temperature is 110 degrees C, the ramp rate is 7 degrees C/minutes to a final oven temperature of 280 degrees C and held for 20 minutes. For analyte identification, the extracted ion current profiles of the primary m/z and the confirmatory ion for each analyte must be at a maximum in the same scan or within one scan of each other and the retention time must fall with 5 seconds of the retention time of the authentic standard.

Summary of Method 1613B

This procedure uses matrix specific extraction, analyte specific cleanup, and HRGC/HRMS analysis techniques for dioxins and furans.

If interferences are encountered, the method provides selected cleanup procedures to aid the analyst in their elimination.

A specified amount of sample is spiked with a solution containing specified amounts of each of the fifteen isotopically labeled PCDDs/PCDFs. The sample is then extracted according to a matrix specific extraction procedure. Aqueous samples that are judged to contain 1 percent or more solids, and solid samples that show an aqueous phase, are filtered, the solid phase (including the filter) and the aqueous phase extracted separately, and the extracts combined before extract cleanup.

The extraction procedures are:

 Toluene: Soxhlet extraction for soil, sediment, fly ash, and paper pulp samples;

 Methylene chloride, liquid-liquid extraction for water samples

 Toluene: Dean-Stark extraction for fuel oil, and aqueous sludge samples;

 Toluene extraction for still bottom samples;

 Hexane/methylene chloride, Soxhlet extraction or methylene chloride, Soxhlet extraction for fish tissue samples

 Methylene chloride extraction for human adipose tissue samples

As an option, all solid samples (wet or dry) may be extracted with toluene using a Soxhlet/Dean Stark extraction system. The decision for the selection of an extraction procedure for chemical reactor residue samples is based on the appearance (consistency, viscosity) of the samples. Generally, they can be handled according to the procedure used for still bottom (or chemical sludge) samples.

The extracts are submitted to an acidic washing treatment and dried. Following a solvent exchange step, the extracts are cleaned up by column chromatography on silica gel and activated carbon. The extracts from adipose tissue samples are treated with silica gel impregnated with sulfuric acid before chromatography on acidic silica gel, and activated carbon.

Fish tissue and paper pulp extracts are subjected to an acid wash treatment only, prior to chromatography on alumina and activated carbon.

The preparation of the final extract for HRGC/HRMS analysis is accomplished by adding 20µL of a nonane solution containing 100pg/µL of the internal standard compounds, 13C12 -1,2,3,4-TCDD and 13C12 -1,2,3,7,8,9-HxCDD. The former is used to determine the percent recoveries of tetra- and pentachlorinated PCDD/PCDF congeners, while the latter is used to determine the percent recoveries of the hexa-, hepta- and octachlorinated PCDD/PCDF congeners.

Two µL of the concentrated extract are injected into an HRGC/HRMS system capable of performing selected ion monitoring at resolving powers of at least 10,000 (10 percent valley definition).

The identification of sixteen 2,3,7,8-substituted congeners, for which a 13C12-labeled standard is available in the sample and the labeled standard spiking solutions, is based on their elution at their exact retention time (within 0.005 retention time units measured in the routine calibration) and the simultaneous detection of the two most abundant ions in the molecular ion region. The identification of OCDF is based on its retention time relative to
13C12 -OCDD and the simultaneous detection of the two most abundant ions in the molecular ion region. Identification is also based on a comparison of the ratios of the integrated ion abundance of the molecular ion species to their theoretical abundance ratios.

Quantitation of the individual congeners, total PCDDs and total PCDFs is achieved in conjunction with the establishment of a multipoint (five points) calibration curve for each homologue, during which each calibration solution is analyzed once.

Tissue Extraction Method (PAH and OCs)

Tissue samples are either immediately processed or stored frozen (-20°C) until processing. Tissues are processed as appropriate for the tissue type (e.g. dissection, shucking). Processed tissues are homogenized using a variety of mechanical methods (Waring blender, Hobart meat grinder or Tissumisser), depending upon the tissue amount and type. After homogenization, an approximate 1 g aliquot is removed and dried in an oven at 105°C to a constant weight to determine % moisture. The remaining samples are stored in certified pre-cleaned jars frozen (- 20°C) until analysis. Prior to extraction, tissue samples may be lypholized or a wet aliquot is chemically dried using a dessicant such as Hydromatrix or sodium sulfate. Samples are then extracted using a Dionex ASE200 Accelerated Solvent Extractor (ASE). The dried sample or the sample and dessicant material is loaded into 22 or 33 mL stainless steel ASE extraction tubes. The extraction are performed using 100% dicholormethane at 100°C and 2000 psi. The extracted organics dissolved in the solvent are collected in 60 mL glass vials. The extract is concentrated to approximately 10 mL in the collection vials and then transferred to 25 mL Kurdena-Danish (KD) concentrator tubes. The sample extract is concentrated to 3 mL in a water bath at 55-60°C. If lipid weight is required, a 100 mL aliquot is removed and weighed using a microbalance. Interfering non-contaminant organic material (primarily lipids) must be removed prior to instrument analyses.

The extract is processed through silica gel/alumina chromatography columns and High Performance Liquid Chromatography (HPLC). The remaining 2.9 mL of sample extracted are loaded on top of 300 mm x 19 mm glass liquid chromatography columns packed with 10 g of deactivated alumina and 20 g of deactivated silica gel. The columns are loaded in 100 % dichloromethane. The dichloromethane is replaced by adding 40 mL of pentane. The extract is carefully added to the top of the chromatography columns. The column is flushed at a rate of 1-2 mL per minute using 200 mL of 50:50 pentane/dichloromethane and collected into 250 mL flasks. The eluent collected in the 250 mL flask is evaporated to 2 mL using a waterbath at 55-50°C. The samples is transferred into 4 mL amber vials. Extracts subsequently processed by HPLC to further remove lipid interferences. Lipid removal is accomplished by flushing samples with dichlormethane through size exclusion Phenogel 10 m GPC 100 A columns. Approximately 40 mL is collected using a fraction collector, which is concentrated to 0.5 mL using a water bath at 55-60C. The concentrated extract is then analyzed by GC/MS for polynuclear aromatic hydrocarbons (PAHs) or GC/ECD for selected organochlorines (OCs).

Additional column chromatography is required to separate PCBs from toxaphene/pesticides when toxphene analysis is required and to separate planar PCBs. If toxaphene analyses is required, an aliquot of the extract prior to HPLC clean up is processed through a 3% deactivated silica gel column. The column is packed in dicloromethane which is then flushed with 50 mL of pentane. The sample extract is transferred to the top of the column and flushed with 100 mL of pentane. The fraction contains PCBs and DDTs. The column is then flushed with 120 mL of 50:50 pentane/dichloromethane. This fraction contains toxaphene and chlorinated pesticides. Both fractions are reduced to 1 mL using a water bath at 55-60°C. The extracts are then ready for instrument analysis.

If planar PCB analyses are required, the PCB/DDT fraction prepared by 3% silica gel column is further processed by column chromatography packed with 2 g of 1:19 (5% by weight) mixture of activated carbon/Celite. The column and flushed with 25 mL of 1:4 dichloromethane/cyclohexane mixture. The sample is added to the top of the column and flushed with 50 mL of 1:4 dichloromethane/cyclohexane mixture, followed by 30 mL of 9:1 dichloromethane/toluene. This is followed by the addition of 40 mL

of toluene. The toluene fraction contains the planar PCBs and is concentrated to 1 mL in a Zymark TurboVap II concentrator at 42°C and 20 psi. The sample is ready for instrument analysis.

Summary of Method 1668A

This procedure uses matrix specific extraction, analyte specific cleanup, and HRGC/HRMS analysis techniques for PCB congeners.

Aqueous samples (samples containing less than one percent solids) ¨C Stable isotopically labeled analogs of the toxics and labeled earliest and latest level of chlorination (LOC) PCBs are spiked into the sample aliquot. The sample is extracted using a separatory funnel extraction and concentrated for clean up.

Solid, semi-solid, and multi-phase samples (excluding tissue) ¨C The labeled compounds are spiked into sample material that corresponds to approximately 5g on a dry weight basis. For samples with high moisture content, the amount of wet weight material to add the labeled compounds to would necessarily be greater than 5g. All samples are homogenized properly and extracted in a Soxhlet extraction apparatus or Accelerated Solvent Extractor (ASE). The extract is concentrated for clean up.

Fish and other tissue ¨C An aliquot of tissue sufficient enough to provide sample for PCB and lipid analysis is homogenized and spiked with labeled compounds. The sample is mixed with anhydrous sodium sulfate, allowed to dry for 12-24 hours, and extracted for 16-24 hours using a 1:1 dichloromethane/hexane solution in a Soxhlet extraction apparatus. The extract is split; with one aliquot concentrated for clean up and the other concentrated for lipid determination.

After extraction, a labeled clean up standard is spiked into the extract which is then cleaned up using back-extraction with sulfuric acid and/or base, and silica gel or Florisil chromatography.

After clean up, the extract is concentrated to 20¦ÌL. Immediately prior to injection, labeled injection internal standards are added to each extract and an aliquot of the extract is injected into the gas chromatograph (GC). The analytes are separated by the GC and detected by a high resolution (¡Ý10,000) mass spectrometer. Two exact m/z¡¯s are monitored at each level of chlorination throughout a pre-determined retention time window.

An individual PCB congener is identified by comparing the GC retention time and ion-abundance ratio of two exact m/z¡¯s with the corresponding retention time of an authentic standard and the theoretical or acquired ion-abundance ratio of the two exact m/z¡¯s. Isomer specificity for certain of the CB congeners is achieved using GC columns that resolve these congeners.

Quantitative analysis is performed in one of two ways using selected ion current profile (SICP) areas:

For the toxics and the earliest and latest level of chlorination CBs (Toxics/LOC), the GC/MS is multi-point calibrated and the concentration is determined using the isotope dilution technique.

For all other congeners, the GC/MS is calibrated at a single concentration and the concentrations are determined using the internal standard technique.

For the labeled congeners, the GC/MS is calibrated using replicates at a single concentration and the concentrations of these labeled compounds are determined using the internal standard technique.

The quality of analysis is assured through reproducible calibration and testing of the extraction, clean up and GC/MS systems.

Water Extraction Method (PAH and OC)

Water samples are either immediately processed or stored refrigerated (4 degrees C) until processing. The pH of samples is adjusted to <2 by the addition of 1 mL of hydrochloric acid. Samples are serially extracted using separatory funnels and dichloromethane. For a 1 L sample, 100 mL of dichloromethane is added. The sample is then shaken for three minutes. The organic layer is allowed to separate from the aqueous phase. The organic layer is drained into a 500 mL round bottom flask

through a glass funnel containing a glass fiber filter and combusted sodium sulfate. This process is repeated twice more. The extract is concentrated to approximately 10 mL in the 500 mL round bottom flasks in a water bath at 55-60 degrees C and then transferred to 25 mL Kurdena-Danish (KD) concentrator tubes. The sample extract is concentrated to 3 mL in a water bath at 55-60 degrees C. If extractable organic material weight is required, a 100 micro litter aliquot is removed and weighed using a microbalance. Interfering non-contaminant organic materials may be removed prior to instrument analyses.

If the extract is colored then sample clean up may be required. The extract is processed through silica gel/alumina chromatography columns. The sample extract is loaded on top of 300 mm x 19 mm glass liquid chromatography columns packed with 10 g of deactivated alumina and 20 g of deactivated silica gel. The columns are loaded in 100 % dichloromethane. The dichloromethane is replaced by adding 40 mL of pentane. The extract is carefully added to the top of the chromatography columns. The column is flushed at a rate of 1-2 mL per minute using 200 mL of 50:50 pentane/dichloromethane and collected into 250 mL flasks. The eluent collected in the 250 mL flask is evaporated to 2 mL using a waterbath at 55-50 degrees C. The samples is transferred into 2 mL amber vials. The concentrated extract is then analyzed by GC/MS for polynuclear aromatic hydrocarbons (PAHs) or GC/ECD for selected organochlorines (OCs).

Additional column chromatography may be required to separate PCBs from toxaphene/pesticides when toxphene analysis is required and to separate planar PCBs. If toxaphene analyses is required, an aliquot of the extract after silica/alumina clean-up is processed through a 3% deactivated silica gel column. The column is packed in diclorometh ane which is then flushed with 50 mL of pentane. The sample extract is transferred to the top of the column and flushed with 100 mL of pentane. The fraction contains PCBs and DDTs. The column is then flushed with 120 mL of 50:50 pentane/dichloromethane. This fraction contains toxaphene and chlorinated pesticides. Both fractions are reduced to 1 mL using a water bath at 55-60 degrees C. The extracts are then ready for instrument analysis.

If planar PCB analyses are required, the PCB/DDT fraction prepared by 3% silica gel column is further processed by column chromatography packed with 2 g of 1:19 (5% by weight) mixture of activated carbon/Celite. The column and flushed with 25 mL of 1:4 dichloromethane/cyclohexane mixture. The sample is added to the top of the column and flushed with 50 mL of 1:4 dichloromethane/cyclohexane mixture, followed by 30 mL of 9:1 dichloromethane/toluene. This is followed by the addition of 40 mL of toluene. The toluene fraction contains the planar PCBs and is concentrated to 1 mL in a Zymark TurboVap II concentrator at 42 degrees C and 20 psi. The sample is ready for instrument analysis.

LABORATORY: TDI Brooks International, Inc

Summary of Method 1668A

This procedure uses matrix specific extraction, analyte specific cleanup, and HRGC/HRMS analysis techniques for PCB congeners.

Aqueous samples (samples containing less than one percent solids) ¨C Stable isotopically labeled analogs of the toxics and labeled earliest and latest level of chlorination (LOC) PCBs are spiked into the sample aliquot. The sample is extracted using a separatory funnel extraction and concentrated for clean up.

Solid, semi-solid, and multi-phase samples (excluding tissue) ¨C The labeled compounds are spiked into sample material that corresponds to approximately 5g on a dry weight basis. For samples with high moisture content, the amount of wet weight material to add the labeled compounds to would necessarily be greater than 5g. All samples are homogenized properly and extracted in a Soxhlet extraction apparatus or Accelerated Solvent Extractor (ASE). The extract is concentrated for clean up.

Fish and other tissue ¨C An aliquot of tissue sufficient enough to provide sample for PCB and lipid analysis is homogenized and spiked with labeled compounds. The sample is mixed with anhydrous sodium sulfate, allowed to dry for 12-24 hours, and extracted for 16-24 hours using a 1:1 dichloromethane/hexane solution in a Soxhlet extraction apparatus. The extract is split; with one aliquot concentrated for clean up and the other concentrated for lipid determination.

After extraction, a labeled clean up standard is spiked into the extract which is then cleaned up using back-extraction with sulfuric acid and/or base, and silica gel or Florisil chromatography.

After clean up, the extract is concentrated to 20¦ÌL. Immediately prior to injection, labeled injection internal standards are added to each extract and an aliquot of the extract is injected into the gas chromatograph (GC). The analytes are separated by the GC and detected by a high resolution (¡Ý10,000) mass spectrometer. Two exact m/z¡¯s are monitored at each level of chlorination throughout a pre-determined retention time window.

An individual PCB congener is identified by comparing the GC retention time and ion-abundance ratio of two exact m/z¡¯s with the corresponding retention time of an authentic standard and the theoretical or acquired ion-abundance ratio of the two exact m/z¡¯s. Isomer specificity for certain of the CB congeners is achieved using GC columns that resolve these congeners.

Quantitative analysis is performed in one of two ways using selected ion current profile (SICP) areas:

For the toxics and the earliest and latest level of chlorination CBs (Toxics/LOC), the GC/MS is multi-point calibrated and the concentration is determined using the isotope dilution technique.

For all other congeners, the GC/MS is calibrated at a single concentration and the concentrations are determined using the internal standard technique.

For the labeled congeners, the GC/MS is calibrated using replicates at a single concentration and the concentrations of these labeled compounds are determined using the internal standard technique.

The quality of analysis is assured through reproducible calibration and testing of the extraction, clean up and GC/MS systems.

Appendix 3C. Complete Catalog 2020128 of Rio Grande silvery minnow carcasses and collection information.

ECDMS Complete Catalog - 2020128

FWS Refuge Names

The results of this catalog are directly applicable to the following FWS refuges:
Bosque Del Apache National Wildlife Refuge , New Mexico
Sevilleta National Wildlife Refuge , New Mexico

Catalog Description
Catalog Instructions
The priority where samples have multiple chemical analyses requested is 209 PCB by HRGC/HRMS, lipids, organochlorine pesticides, heavy metals (and As, Hg, Se), PBDEs, dioxins, aromatics and then other analytes. Note that the fish was dissected and stored in a freezer for up to 2 years, and therefore, moisture content has likely largely been lost and is NOT a priority for analysis although this "analyte" has been requested.

Sample Comments
These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments

Sex	Mixed (composite)	**Age**	Adult
Egg Condition	N/A		
Taxonomical Group	Fish		
Common Name	Rio Grande Silvery Minnow		
Family	Cyprinidae		
Genus / Kingdom	Hybognathus / Animalia		
Species	Hybognathus amarus		

Specimen Abnormalities *(These observations were not necessarily determined by a pathologist)*
N/A

Sample Comments
These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments
Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.
Analysis Requested Comments
Please homogenize and composite all minnow in a sample. For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Species	Hybognathus amarus		

Specimen Abnormalities *(These observations were not necessarily determined by a pathologist)*
N/A

Sample Comments
These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments
Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.
Analysis Requested Comments
Please homogenize and composite all minnow in a sample. For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments
Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.
Analysis Requested Comments
Please homogenize and composite all minnow in a sample. For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Sample Comments

These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments

Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.

FWS Refuge Names

The results of this catalog are directly applicable to the following FWS refuges:
Bosque Del Apache National Wildlife Refuge , New Mexico
Sevilleta National Wildlife Refuge , New Mexico

Catalog Description
Catalog Instructions
The priority where samples have multiple chemical analyses requested is 209 PCB by HRGC/HRMS, lipids, organochlorine pesticides, heavy metals (and As, Hg, Se), PBDEs, dioxins, aromatics and then other analytes. Note that the fish was dissected and stored in a freezer for up to 2 years, and therefore, moisture content has likely largely been lost and is NOT a priority for analysis although this "analyte" has been requested.

N/A

Sample Comments
These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Sex	Mixed (composite)	**Age**	Adult
Egg Condition	N/A		
Taxonomical Group	Fish		
Common Name	Rio Grande Silvery Minnow		
Family	Cyprinidae		
Genus / Kingdom	Hybognathus / Animalia		
Species	Hybognathus amarus		

Specimen Abnormalities *(These observations were not necessarily determined by a pathologist)*
N/A

Sample Comments
These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments
Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.
Analysis Requested Comments
For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Analysis Requested

Organic Analysis
PBDE - Polybrominated Diphenly Ethers

Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments

Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.

Analysis Requested Comments

Please homogenize and composite all minnow in a sample. For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Sample Comments

These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments
Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.

Taxonomical Group	Fish		
Common Name	Rio Grande Silvery Minnow		
Family	Cyprinidae		
Genus / Kingdom	Hybognathus / Animalia		
Species	Hybognathus amarus		

Specimen Abnormalities *(These observations were not necessarily determined by a pathologist)*
N/A

Sample Comments
These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments
Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.
Analysis Requested Comments
Please homogenize and composite all minnow in a sample. For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Egg Condition	N/A		
Taxonomical Group	Fish		
Common Name	Rio Grande Silvery Minnow		
Family	Cyprinidae		
Genus / Kingdom	Hybognathus / Animalia		
Species	Hybognathus amarus		

Specimen Abnormalities *(These observations were not necessarily determined by a pathologist)*
N/A

Sample Comments
These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments
Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.
Analysis Requested Comments
Please homogenize and composite all minnow in a sample. For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Bosque Del Apache National Wildlife Refuge , New Mexico
Sevilleta National Wildlife Refuge , New Mexico

Catalog Description
Catalog Instructions
The priority where samples have multiple chemical analyses requested is 209 PCB by HRGC/HRMS, lipids, organochlorine pesticides, heavy metals (and As, Hg, Se), PBDEs, dioxins, aromatics and then other analytes. Note that the fish was dissected and stored in a freezer for up to 2 years, and therefore, moisture content has likely largely been lost and is NOT a priority for analysis although this "analyte" has been requested.

Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.
Analysis Requested Comments
For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Species	Hybognathus amarus		

Specimen Abnormalities *(These observations were not necessarily determined by a pathologist)*
N/A

Sample Comments
These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments
Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.

Analysis Requested Comments
For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Specimen Information

Sex	Mixed (composite)	**Age**	Adult
Egg Condition	N/A		
Taxonomical Group	Fish		
Common Name	Rio Grande Silvery Minnow		
Family	Cyprinidae		
Genus / Kingdom	Hybognathus / Animalia		
Species	Hybognathus amarus		

Specimen Abnormalities *(These observations were not necessarily determined by a pathologist)*
N/A

Sample Comments
These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments
Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.
Analysis Requested Comments
Please homogenize and composite all minnow in a sample. For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Sex	Mixed (composite)	**Age**	Adult
Egg Condition	N/A		
Taxonomical Group	Fish		
Common Name	Rio Grande Silvery Minnow		
Family	Cyprinidae		
Genus / Kingdom	Hybognathus / Animalia		
Species	Hybognathus amarus		

Specimen Abnormalities *(These observations were not necessarily determined by a pathologist)*
N/A

Sample Comments
These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments
Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.
Analysis Requested Comments
Please homogenize and composite all minnow in a sample. For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Analysis Requested

Organic Analysis
209 PCB by HRGC/HRMS (EPA 1668a)
Organochlorine Scan (OC)
PBDE - Polybrominated Diphenly Ethers
PCB Quantification of Individual Aroclors
Inorganic Analysis
Metals Scan

During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Field Preparation Comments

Seine collection, kept alive, subdued by blow to head, dissected for observations, gonads removed, individual frozen in foil, then all from site removed and composited for chemical analyses.

Analysis Requested Comments

Please homogenize and composite all minnow in a sample. For those samples with multiple analyses, the priority for results is the 209 PCB by HRGC/HRMS, then the Organochlorine scan (with determination of percent lipids is Priority 2), then determination of PBDE and/or dioxin/furan, then the Metal Scan and/or methyl mercury is Priority 4 (moisture content is also requested but is not a priority).

Sample Comments
These Rio Grande silvery minnow were seined from the Rio Grande at various sites and dates. They were held in a live well until necropsy. After being subdued by a blow to the head, individual health observations were made and recorded elsewhere. The gonads were removed for histopathology. During the necropsy, these organs as well as various fluids were lost from the sample. The remaining innards were tucked back in and each individual fish was wrapped in aluminum foil and stored in freezer for up to 2 years. Up to 30 fish (or more) were then composited into a labeled jar and shipped frozen for chemical analyses.

Abstract: The decline of the federally endangered Rio Grande silvery minnow (RGSM) is associated with physical and hydrologic changes in the Rio Grande system. Decreasing water quality and contaminants may also be factors. This study, as part of a larger study, was designed to evaluate the health of the RGSM in relation to water quality and other environmental stressors in the Rio Grande. Health indicators including somatic indices, gross observation during necropsy, hematology, and histological observations were used to assess the health of wild RGSM seasonally and at several locations along the middle Rio Grande. Both a temporal and spatial relationship was seen. RGSM collected in the summer tended to be less healthy as indicated by: increased macrophage aggregates and granulomas, lowered liver glycogen, and increased spleen size with fewer red blood cells. Whereas silvery minnows from all sites showed impairment, health indicators such as Health Assessment Index (HAI), Splenosomatic Index (SSI), and percentage of fish with 2 or more pathologies showed an upstream to downstream trend, with sites below Albuquerque being less healthy in general. Our results indicate that the RGSM in the reach of critical habitat between Bernalillo, NM and Bosque del Apache National Wildlife Refuge are experiencing chronic stress as evidenced by a suite of health indicators. Given the results from the bioindicators used in this study and the stressors present, it appears that the stress is likely related to poor water and sediment quality (ammonia, metals, bacteria, and possibly PAHs). These results are in agreement and consistent with the known impacts of urban effluents, stormwater runoff, and agricultural return waters.

Keywords: Rio Grande, Rio Grande silvery minnow, health assessment, histopathology

The endangered Rio Grande silvery minnow (*Hybognathus amarus*), once abundant throughout the Rio Grande and Pecos River, is found almost exclusively in a 286-km section of critical habitat in the middle Rio Grande between the Cochiti and Elephant Butte reservoirs. The Rio Grande silvery minnow has been described by Cowley et al. (2006) as a resilient and adaptable species tolerant of low oxygen conditions. It has been determined that it is a benthic herbivore with diatoms comprising an important component of the diet (Magana 2009). Today in the Rio Grande, it is most often found in no- to low-velocity habitats with silted bottoms (USFWS 2007). As an annual pelagophil, it evolved to spawn in spring when Rio Grande discharge increased from headwater snowmelt and seasonal rain events (USFWS 2007). In the contemporary dammed and channelized Rio Grande, spawning is more likely cued on dam releases, and increased run-off from diversion channel flows (Platania and Altenback 1998). Silvery minnow survival in the wild has been determined to be 13 to 25 months, with many dying after only one spawning (USFWS 2007), yet in captivity the RGSM can live 5 to 8 years (Cowley et al. 2006; K. Buhl, pers. comm.).

The demise of Rio Grande silvery minnow populations has been attributed primarily to physical and hydrological changes of the river system (Alò and Turner 2005). However, consistently poor water quality is also believed to be a factor in the decline of this species to the extent that pollution and disease are identified as listing factors in the silvery minnow recovery plan (USFWS 2007). A health assessment of fishes in the Rio Grande conducted in 1997-1998 generalized that study fish from the lower basin (below El Paso) contained greater concentrations of some contaminants and appeared to be less healthy than those from upper basin sites where the silvery minnow is almost exclusively found today (Schmitt et al. 2005). The Elephant Butte Reservoir site from the health assessment (the only site within the silvery minnow critical habitat reach), was considered more contaminated than the site north of critical habitat near the headwaters and also the El Paso site (Schmitt et al. 2005). Elephant Butte

fish had elevated ethoxyresorufin-o-deethylation (EROD) rates and some fish were rated unhealthy and with poor condition factor (Schmitt et al. 2005). More recently, fish sampled between Albuquerque and Elephant Butte were found with lesions, elevated vitellogenin, and slightly elevated EROD levels (Papoulias, unpublished data). Although limited, the existing fish health data and the known water quality information suggest the Rio Grande silvery minnow population could be unhealthy.

Water quality has deteriorated in the middle Rio Grande and adequate flows to support aquatic ecosystems have declined over the past thirty years (Passell et al. 2004, 2005, 2007). The most recent evaluation of water quality in the Middle Rio Grande indicates that quality is insufficient to support warmwater aquatic life. The State of New Mexico CWA Integrated Report (NMED 2008a) identifies low dissolved oxygen, *E.coli*, elevated ammonia, and possibly some heavy metals as reasons for concern. Probable sources of impairment cited include municipal point (e.g., wastewaters) and non-point sources. Such sources are also known to have a plethora of pharmaceuticals and personal care products (Batt et al. 2008; Brown, 2004; Kolpin et al. 2002). In addition, the Rio Grande is heavily used for irrigation (Jackson et al. 2001). Irrigation return waters can increase conductivity, and contain high concentrations of salts, nutrients and trace elements such as arsenic (Norman and Dilley 2002). These potential sources of contaminants together with low flows increase the likelihood that Rio Grande fishes and other aquatic organisms are exposed to stressful and unhealthy conditions.

Continuous exposure to stressors can impair the health of an organism and require it to divert its energy and biological resources away from growth and reproduction and consequently have population-level effects (Schreck et al. 2001). Under chronically stressful conditions fish are more susceptible to pathogens and toxicants which may result in pre-pathological or pathological conditions (Moberg 2000). During fish culture, evaluating fish health at the biochemical, cell, and tissue levels may allow intervention with therapeutic treatments to avoid losses of animals. Assessment and monitoring of the

health of wild populations of fish provides the fisheries biologist with diagnostic information about habitat quality and may indicate specific environmental stressors (de la Torre et al. 2005; Marchand et al. 2009). Monitoring the health of endangered species, especially during reintroduction, restoration and mitigation efforts, is essential to providing scientific information about the success of recovery efforts.

The present study was part of a larger study to evaluate the health of the Rio Grande silvery minnow (RGSM) throughout its designated critical habitat (Lusk 2007). Studies were designed to provide a means to characterize the health status of wild RGSM in relation to water quality and other environmental stressors in the Middle Rio Grande over multiple years, thus capturing variation across seasons. The study included a fish health assessment using somatic indices and systematic observation of fish tissues and organs during necropsy and through histopathology (Goede and Barton 1990; Schmitt et al. 1999; Schmitt and Dethloff 2000; Smith et al. 2002). Therefore, objectives of this portion of the study were to assess the health of the RGSM seasonally at several locations using somatic indices, hematology, and histopathology.

Methods and Procedures

Six sites (Table 1) within the Middle Rio Grande were sampled during 2006-2007 (Year 1) and 2007-2008 (Year 2). Thirty fish were targeted for collection at each site to provide sufficient material for all analyses of the larger study. Site 1 was above the city of Albuquerque, Site 2 was geographically above Albuquerque but below the city's main municipal storm runoff diversion channel outflow, and Sites 3 – 6 were below Albuquerque. Site 1, the furthest upstream site served as a less impacted reference site and Site 3 is immediately downstream of the Albuquerque wastewater treatment plant discharge and other smaller tributaries. Collection efforts were conducted under stable flow conditions. Fish were held in aerated live wells until processed. Fish health assessments were performed in a laboratory within several hours after capture. All collected fish were individually measured for body

weight and total length, followed by visual determination of sex, examination for external and internal abnormalities, and removal and weighting of spleens. Total body weight and spleen weight were used to calculate a Splenosomatic Index (SSI) for each fish that had a recorded spleen measurement; though some were too small. Somatic indices can reflect the status of organ systems, which may change in size due to environmental stressors (Busacker et al. 1990). A Health Assessment Index (HAI) was also calculated as a general indicator of fish health (Adams 1990; Carlander 1969, 1977). Developed and revised by Goede (1988, 1989, 1996), HAI utilizes observations of gross external and internal pathological disorders (see Schmitt and Dethloff 2000 for a complete description). On a sub-sample of RGSM collected liver, spleen, kidney, gonad, and gill were dissected for histopathology.

Opercula of the collected fish were observed for shortening on one or both opercula. For analysis, shortened opercula were assessed as present/absent rather than the degree of shortening to assist in reducing the subjective nature of opercula observation. As part of this study we also evaluated the incidence of shortened opercula in archived RGSM samples from the University of New Mexico, Museum of Southwestern Biology (Accession Number ACC2006-VII:31). Archives contain preserved RGSM from 1938 to 2001. The following cataloged collections of RGSM at the Museum of Southwestern Biology were examined for shortened opercula: 1119, 1120, 1125, 1130, 1151, 1155, 1162, 1171, 3961, 4338, 4384, 5730, 5934, 11589, 13472, 20396, 22671, 30032, 30246, 39103, 45271, 43314, 44627, 48229, and 49969. Right and left opercula of 30 fish from each year for 25 years between 1938 and 2001 were randomly selected, measured for weight and length, and observed for degree of operculum shortening. The degree was noted as slight or severe. Slight shortening is described as visible shortening with flap obviously not covering entire gill with a minimal amount of gill exposed. Severe shortening is described as extreme shortening with the gill exposed and visible to the un-aided eye.

Histopathology

Tissues for histopathology were collected from three individuals at each of the six sites during Year 1 and six individuals at each of the six sites Year 2. Liver, kidney, spleen, gonad, and gill were removed and placed in 10% neutral buffered formalin (NBF). All tissues from an individual were mixed in one vial during Year 1 and this resulted in loss of some of the very small organs (i.e., spleen, kidney, and testes). Therefore, in Year 2, we removed the entire viscera to one vial and placed kidneys and gonads in separate vials. A limited number of opercula were also processed for histology or cleared for staining of bone and cartilage following Kelly and Bryden (1983) for in-depth examination of shortening of the distal margin. Processing for histology consisted of rinsing tissues in two changes of 10 mM HEPES buffer (pH 7.4) and dehydration by immersion in graded aqueous ethanol solutions ranging from 50% to 100%. Gill and opercula were decalicified in Surgipath® Decalcifier II solution prior to processing. This was followed by immersion in xylene and subsequent infiltration with paraffin. The paraffin-embedded samples were sectioned at 5 μm, mounted onto silanized slides, and stored at room temperature until staining. In preparation for histochemical staining, tissue sections were de-waxed with xylene and then rehydrated to water by immersion in graded solutions containing decreasing concentrations of ethanol from 100% to 0%. Tissue samples were stained following the general nuclear stain procedure for hematoxylin and eosin (Luna 1968).

Macrophage aggregates (MAs) are part of the fish's defensive system against foreign matter or infectious disease (Wolke et al. 1985) and have been used as biomarkers of contaminant exposure. Numbers and areas of MAs were assessed on three sections of spleen tissue from each fish and reported per area of spleen. MAs were enumerated on sections of spleen stained with hematoxylin and eosin on an inverted Nikon Diaphot using a 10x objective and Optimas® image analysis software. MAs in some samples were too small to determine area and were only counted.

Light microscopy was used to qualitatively evaluate the tissues for lesions and pathologies. We used RGSM collected from Dexter National Fish Hatchery and Technology Center (Dexter, NM) for a reference set of healthy organs/tissues for qualitative comparisons. Gonads were also assigned sex and stage of reproductive maturity (see Blazer 2002 for description).

Haematology

Analysis of the ratio of leukocytes was made on touch smears of head and trunk kidneys, spleen, and liver for 2 sites in one season. August 8, 2008 six RGSM were caught at Site 1 (relative reference location) and at Site 3. Fish were pithed and organs removed. Each freshly dissected organ was blotted three times onto uncoated microscope slides then preserved by immersion in 95% ethanol for 20 minutes. After air-drying, the slides were later stained using Romanovsky–Giemza stain. Using light microscopy, eight leukocyte types were identified and enumerated according to the classification of Ivanova (1983). Not less than 200 cells were evaluated on each slide.

Statistics

Statistics were computed on the full set of sampled fish for mean length, weight, opercula shortening, SSI and HAI. Weight and length differences between years were tested as well as weight, length, and index differences in combined years to determine site- and month-specific differences. Age and sex can influence size of spleen, therefore length as a surrogate of age was tested for covariance with SSI and sex was included as a second factor with station in an analysis of variance. We tested for site- and month-specific differences in the percent of fish with shortened opercula for each sampling year. A t-test was used to determine if archived fish with shortened opercula differed in size from fish without shortened opercula. Site-specific percent occurrence of the subset of total fish examined for tissue condition, pathology, or fish's sex (determined with histology) was calculated for each sampling

date and means for sites or months were tested for differences. Data were combined for the two years for testing of seasonal and site differences for these measures because few fish were evaluated at each site in a given year. Data were analyzed using SAS v.9.2 software (SAS Institute Inc., Cary, NC, USA). All data were tested for homogeneity of variances (Levene's test) and normality (Shapiro-Wilk statistic). Percentage data were arcsin transformed and SSI data were log-transformed. A general linear model with LSMEANS as the post-hoc comparison test was used to test for site and month differences unless data did not meet assumptions for parametric tests after transformations; then we used the non-parametric Wilcoxon signed-ranks. Macrophage aggregate count and area measures were tested for covariance with estimated fish age prior to analysis of variance among sites. Age was estimated by converting total length to standard length using the formula (SL=1.0182(TL)-10.909) followed by estimation of age from the formula cited by Cowley et al. (2006). The Mantel-Haenszel Chi-Square for trends was used to evaluate trend in percent females upstream to downstream. Leukocytes were analyzed using a t-test and reported as percentage of 200 cells. There are no reported normal health indicators for silvery minnow. Therefore for these studies, fish from Site 1 were considered relative normal and individuals captured at other sites were compared against results from Site 1.

Results

A total of 1,070 RGSM were observed during two years of study. Overall, RGSM collected in Year 1 were larger (70 ± 11 mm Total Length (TL) n = 511, 3.1 ± 1.5 g, n = 516) than those collected in Year 2 (59 ± 11 mm TL n = 554, 1.9 ± 1.0 g, n = 553; $p < 0.001$). There were also significant differences in weights and lengths among months ($p<0.012$) and sites ($p<0.0001$). RGSM were smallest at Sites 1 and 2 and largest in October (Figures 1 and 2). There was no influence of sex on the site- or

month-specific weights or lengths. Neither mean length, mean weight, nor length-weight regression curves were different between males and females (data not shown).

Sex did not influence the effect of site or month on mean SSI values. Length did covary with SSI therefore all SSI analyses were adjusted for length. SSIs were greatest in July and October, and smallest in January and April ($p = 0.0001$). Mean SSIs for Sites 1,2, and 3 were larger than for Sites 4 and 5. Site 1 mean SSI was also larger than Site 6 mean SSI ($p=0.02$) (Figure 3). There was also a significant interaction between site and month ($p<0.0001$). Mean SSIs of fish within Sites 4, 5, and 6 did not significantly differ during any month and in January there were no differences in SSI among sites. Mean SSIs for fish collected at Sites 1 and 2 were greatest in July compared to other months and during July and October at Site 3. At Sites 4 and 5 mean SSIs in October were larger than those in July at these sites. In April, fish at Sites 1 and 2 had similar SSIs but mean site values were larger than for Site 3. In July, mean SSIs of fish at Sites 4 and 5 were smaller than mean SSIs for fish at Sites 1, 2, and 3. In October, mean SSI for fish at Site 3 was larger than that for fish at any other site. At Site 3, Year 2, a single fish with an SSI of 2.89, was recorded.

Rio Grande silvery minnow HAI scores were significantly greater in July compared to other months ($p = 0.05$) for both years combined. Site 3 HAI score was greater than Sites 1 and Site 2 ($p < 0.0491$). Mean HAI scores tended to increase downstream to Site 3 and remain similarly elevated downstream to Site 6 (Figure 4).

Pathology

A total of 573 tissue samples of kidney, liver, spleen, gonad, and gill from a total of 147 fish were submitted for histology from July 2006 to July 2008. As a result of a malfunction with the tissue processing equipment, most of the April 2007 samples and all gill samples from October 2006, January 2007, and April 2007 were damaged and unusable. Few types of histological abnormalities were seen

in gonad, spleen, and liver. A greater percentage of fish had kidney and gill abnormalities. For all tissues, the total percent of fish with a pathological lesion or those with two or more lesions tended to increase from upstream sites to downstream sites.

Gill

Gross gill abnormalities (discoloration, fraying, clubbing, and parasites) were observed in 35% of fish examined during Year 1 and 50% Year 2. Of the 80 gills examined, only three had no lesions and most, irrespective of site, had multiple lesions. Clubbing, curling, and swelling of secondary lamellae were the most common lesions observed. Fused lamellae, lifting of the epithelium and the lamellae, and embolism were also seen.

Opercula

During Year 1, 50% of fish observed had shortened opercula. Year 2, that percentage increased to 89%. Shortened opercula were the most prevalent gross abnormality. During Year 1, this anomaly was overwhelmingly bilateral (83.2 %) and a unilateral abnormality affected only 2.9% right side and 3.1% left side. Year 2 had a lower bilateral frequency of 40.9% with only frequencies of 3.7% right side and 5.8% left side. Year 1 RGSM had increased overall occurrence during April (68%) and July (65%) and reduced overall occurrence during January (38%). Contradictory to Year 1, Year 2 fish had extremely elevated observations of shortened opercula during January (98%); July and October were slightly lower, 86% and 79%, respectively. During Year 1, downstream Site 5 had the highest frequency of opercula shortening for all months sampled. During Year 2, all six sites had high occurrence (> 70%) of shortened opercula. Historic incidence of shortened opercula similarly indicates year-to-year variation, but an increasing temporal trend is evident (Table 2). Archived silvery minnow

with at least one shortened operculum were shorter in total length (p=0.0115, n=249, mean=55.7 mm, range: 21.0-95.0 mm) than RGSM without a shortened operculum (n=390, mean=58.7 mm, range: 22.0-96.0 mm) but there was no difference in weight between these two groups (p=0.6690). Opercula of cleared and stained fish showed differences between a second or third generation RGSM from Dexter, NM with no or only slightly shortened opercula and a wild fish with shortened opercula from Site 2. The distal margin of the opercula in the Dexter, NM RGSM were thicker and appeared to have a higher bone density than the Site 2 RGSM.

Gonads

Overall, 71 of 123 fish analyzed (58%) were females. The percentage of females did not significantly differ between years ($p = 0.3284$) among sites ($p = 0.0931$) or months ($p = 0.3974$), however there was a significant ($p < 0.0001$) trend of progressively more females in samples at sites from upstream to downstream (Figure 5). Based on histological staging of gonads, RGSM appear to be group synchronous batch spawners. Spawning occurred at some time between April and July as we found most females were at Stage IV in April and spent in July. Thirteen percent of the fish, both sexes, had large fat deposits associated with the gonad; occurrence of fat was not seemingly related to month but the majority of these fish were found in Year 1 collections. All but four ovaries (from Sites 2 and 5) with atretic oocytes were also spent. Parasites were only occasionally seen. One testis collected 6 July 2007 had two ovoid structures associated with it that could have been cross-sections of cestodes, cortical alveolar oocytes, or something else (e.g., cross- tissue contamination). A positive identification was not possible.

Liver

Gross liver abnormalites were high for both years. Forty-five percent of fish Year 1 and 59% Year 2 were reported to be discolored or as having a 'mushy' texture. A subset of 147 livers was processed for histopathology. The majority of these livers were low or moderate in glycogen content. There were no site differences but overall, livers of fish caught in July were low in glycogen ($p = 0.0294$). Pathologies were overall low (edema, high fat content, pigments associated with macrophages, granulomas, inflammation, parasites). There was no significant difference among sites or months in incidence of fish having one or more pathologies (Figure 6). Parasites were uncommon all years, but granulomas and MAs were prevalent in July, 2008; hemosiderin and melanin pigments were more common in livers from Year 2 samples. July of Year 1, 53% of the samples had fatty deposits outside of the liver and also fat vacuoles inside of hepatocytes. Sites 2, 3, and 4 all had fish with granulomas but they were most common in Sites 3 and 4 fish; only Site 2 fish also had macrophage aggregates. Nine samples had oocytes associated with the liver. One of these was definitely due to carryover contamination during tissue processing, but from October 2007 forward ovaries were isolated from livers for processing, so this does not explain all observations. The others may be ectopic oocytes, but it is difficult to say with certainty. In some cases, it appears as if the liver tissue partially surrounded the oocytes or they were embedded in fat that was attached to the outside of the liver. It is possible that ovarian tissue had adhered to the outside of the liver and was included in the dissected liver sample.

Spleen

Gross spleen abnormalites (nodules, granular texture, size) decreased from 24% in Year 1 to 11% during Year 2. A subset of 125 spleens was processed for histopathology. In the majority of fish, blood content was either low or moderate and there were no significant site differences whether or not we controlled for month. A greater percentage of RGSM spleens collected in January were perfused

with blood than the other months (p = 0.0092). The incidence of finding fish with a pathological condition (parasite, granuloma, fat, MA) in the spleen was not significantly different among sites (Figure 6). However, Year 1 fish were notably different from Year 2 fish because of the presence of fish with fatty spleens, particularly in July. Twelve percent of the total fish inspected had sparsely pigmented granulomas that may have been caused by bacterial or fungal infection. All granulomas occurred in fish sampled in Year 2. Granulomas were found in fish from all sites, but Site 6 had the most fish with granulomas and Site 5 the fewest. Only one parasite (unidentified) was observed. Macrophage aggregates were most numerous at Site 3 and least abundant at Site 1 but these results were highly variable within a site and not significant among sites (p = 0.1062, no site*month interactions; Table 3). Macrophage aggregates (count and area) were more numerous in July and least in April (p = 0.005), no month*site interactions; data not shown). Estimated age was not a significant covariate with either count or area (n=115, R^2=-0.09, p=0.35 and n=72, R^2=0.04, p=0.76, respectively).

Kidney

Gross kidney abnormalities (size, color, texture, and parasites) were observed in 16% of fish examined during Year 1, increasing slightly to 24% during Year 2. A subset of 117 kidneys was processed for histopathology (pigment, tubular degeneration, regeneration, fat, parasites, and granulomas). In contrast to Year 2, nearly all samples from Year 1 had hemosiderin pigment or melanin or both and a high percentage of fish (36%) had fat associated with the kidneys either surrounding it or infiltrated in the interstitium. Two fish from Year 1 appeared to have ectopic oocytes in the kidney parenchyma, but similarly to the liver this could not be definitively concluded. Several fish (11 total; all sites represented) were collected with kidneys containing many sparsely pigmented granulomas that may have been caused by bacterial or fungal infection. Another fish, collected 6 October 2006 from Site 3, showed production of an inordinate number of segmented leukocytes in the hematopoietic tissue

suggesting that the fish may have had a systemic or other infection. The incidence of finding fish with a pathological condition in the kidney was not significantly different among sites (Figure 6). Ninety-two percent of the fish collected had degenerating kidney tubules (Figure 7). Some regenerating tubules were observed in Year 2 fish.

Leukocytes

Changes in proportion of leucocytes were observable in Site 3 fish relative to Site 1 fish for all investigated organs (Table 4). Hemocytoblasts were reduced in head kidney, but plasma cells and segmented neutrophils were increased. Plasma cells and segmented neutrophils were also increased in trunk kidney but stab neutrophils were reduced. Lymphocytes were fewer in spleen but macrophages and promyelocytes (immature granulocytes) increased. In the liver, lymphocytes increased but neutrophils decreased.

Discussion

Health assessments have proven useful in evaluating an individual fish's integrated response to environmental stressors. In our study, collection of a small number of fish during different seasons for an extended time assured that a range of biotic and abiotic stressors could manifest through our suite of biological health indicators and also allowed us to more easily discern trends. Health of RGSM surveyed over a period of two years was variable but consistently impaired spatially and temporally. The results showed that RGSM health deteriorated from upstream to downstream within the designated critical habitat and that summer and the months with low river discharge were the most stressful for these fish.

Some of the health effects observed in the RGSM may be explained by the suite of environmental stressors present in the waters of the RGSM critical habitat. *E. coli* is rarely a fish

pathogen. It serves as an indicator of the relative level of organic pollution or mammalian fecal waste. The elevated *E. coli* in the Rio Grande reflects the influence that wastewater treatment plants and residential stormwater run-off have on its water quality. Fish chronically exposed to wastewater effluents experience reproductive, endocrine, immune, genotoxic, and nephrotoxic effects (Liney et al. 2005). Chemicals in these waters include polycyclic aromatic hydrocarbons, metals, natural hormones, and pharmaceuticals, all measured in the Rio Grande and many at levels of concern.

The water quality data collected by NMED (2009) and SWQB (2009) during the same period and at the sites sampled in the present study generally support a trend of poorer water quality (i.e., elevated biological oxygen demand (BOD), total phosphorus, and *E. coli*) from upstream to downstream, during summer months, and low flow periods (Table 5). These same studies also document potentially toxic levels of contaminants (primarily metals) in water, sediment, and fish tissue at many of our study sites. Temperature, pH, and ammonia in the NMED (2009) study rarely exceeded water quality criteria, however, reduction of dissolved oxygen at some locations was of concern. Dissolved concentrations of aluminum and copper exceeded water quality standards for chronic and acute effects at most sites (NMED 2009; Table 5). Total concentrations of aluminum, copper, iron, arsenic, cyanide, and fluoride in water, sediments, or both at some sites and in some seasons (NMED 2009; Table 5) were at potentially toxic levels and among elements identified in a 2005 Rio Grande risk assessment as likely contributing to overall environmental stress to RGSM (Marcus et al. 2005). Several sediment PAHs were measured at levels above screening criteria but only at Sites 2 and 3 (NMED 2009). Fish tissues were elevated for zinc at all sites and for total DDT in fish collected between Sites 1 and 2 and between Sites 2 and 3 (NMED 2009). Analysis for pharmaceuticals and personal care products (PPCP) of effluents from seven wastewater treatment plants within our study site found 36 of 54 PPCP analytes (NMED 2009). Total suspended solids (TSS) were high at many sites

and seasonally (Table 5). Although the Rio Grande has historically had periods of both high and low turbidity (Julien et al 2005; Cowley et al. 2009), the contemporary composition of suspended solids may serve as sinks for pathogens and abiotic contaminants by adsorbing to particle surfaces.

Health Indicators

Organo-somatic indices are simple and inexpensive to perform. Although simplistic compared to other biomarkers, health indices and gross observations can be used as general indicators of fish health and support results of biomarkers and environmental contaminant analyses. Indices have been used extensively in fish health and population assessments as indicators of well being of individual organisms (Adams 1990; Goede and Barton 1990). For this study, only the SSI and HAI were evaluated and utilized as general indicators of fish health. Hepatosomatic index was not included because cyprinids have a dispersed liver and weight measurements prove to be inaccurate if not impossible. Furthermore, gonadosomatic index was not included in this study because of the difficulty in dissescting out and accurately weighing the gonad tissue in such a small fish.

The quantitative HAI utilizes a comprehensive necropsy based fish health assessment of observations of gross external and internal pathological disorders (Adams 1990; Adams et al. 1993; Goede 1988, 1989, 1996). HAI can be a valuable method for estimating cumulative stress, and documenting lesions or abnormalities that have advanced to the point of being grossly visible, and those the public tends to be most concerned about (Adams 1990; Adams et al. 1992; Schmitt and Dethloff 2000). Studies have indicated that fish in severely polluted areas exhibit a higher frequency of gross lesions than those in similar, less polluted areas (Schmitt and Dethloff 2000). Relative HAI results showed that fish from Site 1 had the lowest mean HAI score and that HAI scores were highest in July consistent with SSI results and liver and spleen pathological observations.

The SSI has been incorporated into other monitoring protocols evaluating the Mississippi River (Schmitt 2002), Columbia River (Hinck et al. 2004a), Yukon River (Hinck et al. 2004b), Colorado River (Hinck et al. 2006) as well as the Rio Grande Basin (Schmitt (Ed.) 2004 and Schmitt et al. 2005) and was used in the present study. The SSI can be a useful diagnostic because it is both a hematopoietic and an immune system organ and abnormalities could exhibit effects at the whole-organism level (Anderson 1990; Schmitt and Dethloff 2000). Acute or nonspecific stressors such as temperature changes, hypoxia, extreme exercise, and exposure to chemical contaminants may cause the spleen to contract and reduce in size. An enlarged spleen may suggest disease or an immune system disorder due to increased hypertrophy or proliferation of leukocytes (Anderson 1990; Goede and Barton 1990). Chemicals identified as of concern in the Rio Grande can affect the fish immune system (Harris and Bird 2000; Reynaud and Deschaux 2006; Zelikoff, 1993). The differences in leukocyte profiles and increase in macrophage aggregates, between fish from the reference site (Site 1) and the sites below it support an immunotoxic effect of one or a mixture of the chemicals measured.

In general, SSI was low (< 2%) and variable among sites. SSI values increased to their highest levels in July at Sites 1, 2, and 6 then decreased back to January and April levels in October. At Site 3 highest levels were also in July but no return to low levels in October was observed. Mean SSI seasonal pattern and magnitude was more similar among Sites 1, 2, and 6 and among Sites 4 and 5. The SSI results were generally consistent with the observed histopathology. January SSI values were low and more similar among sites and this is when the majority of spleens from all sites were seen to be perfused with blood. When fish are calm, erythrocyte count in the spleen is high but when a fish is stressed red bloods cells are released from the spleen into the blood (Takashima and Hibiya 1995). July SSI was highest at Site 3 and this site in July also was notable for fat associated with the spleen and increased macrophage aggregates.

Macrophage aggregates have been suggested as possible bioindicators of environmental chemical exposure (Wolke 1992). Macrophage aggregates function in fish to protect the body by 1) recycling iron, 2) storing, destroying, or detoxifying effete material, and 3) through a role in immune response (Aguis 1985). A large number of studies have noted increases in macrophage aggregates in fish from polluted waters (reviewed in Schmitt and Dethloff 2000). The formation of MAs may also be influenced by age, diet, temperature and other factors, therefore cause and effect relationships may be difficult to establish (Blazer et al.1987). Blazer et al. (1987) found that stressed fish had 9 MAs per mm^2 liver tissue while healthy fish had 4 MAs per mm^2. Most RGSM in this study had MAs greater than or close to 9 MAs excepting Site 1, which had an average of 3 macrophage aggregates. Although we did not age the fish, length, as an indirect measure of age, was not associated with number or area. Hemosiderin, lipofuscin/ceroid, and melanin are pigments often found within macrophage aggregates. While the pigments themselves do not damage tissue, they may indicate the health of an organism or its exposure to toxic compounds. Hemosiderin is a by-product of hemoglobin breakdown and lipofuscin and ceroid are considered to be lipid pigments produced by the peroxidation of unsaturated fatty acids. Melanin is also found in some macrophage aggregates but more often it is found outside of them. It may be deposited after destruction of melanocytes or melanophores. It is thought that melanin may be important as a bactericide or to decrease the damage caused by the production of free radicals by phagocytic cells (Ellis 1981). These pigments were observed in all the types of tissues analyzed, however hemosiderin/lipofuscin/ceroid were most prevalent in kidney and spleen and melanin in gonads.

Overall, kidneys presented with the greatest diversity of lesions in the greatest number of individuals examined. Kidney histopathologies were consistent with chronic inflammation. Ubiquitous inflammation in kidneys of RGSM cannot be associated with any single stressor and is most likely a

general response to poor water quality (Carmago and Martinez 2007). The change in ratio of leucocytes in the kidneys results from the increased number of plasma cells relative to stab neutrophils in Site 3, suggests a pronounced antibody-mediated response to environmental stress or a reaction to diseases caused by weakening of an organism. The increase in stab neutrophils, is an indicator of inflammatory processes in the organism. The significant decrease of hemocytoblasts shows the exhaustion of the leukopoiesis. There is a repartition of cells due to the decrease of lymphocytes and an increase of macrophages in the spleen. It also suggests inflammatory events in the organism and is indirectly confirmed by an increase of promyelocytes. At the same time an increase in mature forms of granulocytes was not observed indicating early cell death and their following utilization by macrophages. A rather unusual reaction in the liver was observed i.e. lymphocytes and immature form of neutrophils (promyelocytes and myelocytes) increased, but the mature neutrophils decreased. It is possible this is due to lymphoid infiltration of the organ caused by development of autoimmune disease. Similar changes in leukocyte ratios were observed in organs (head and trunk kidney, spleen, but not liver) of common bream (*Abramis brama* L.) from variably polluted areas of Rybinsk reservoir (Lapirova and Zabotkina. in press).

Bacterial pathogens tend to be high in wastewater-dominated streams and this may be reflected by the types of gill lesions observed (Seeley and Weeks-Perkins 1991). The gills are critical sites for ion regulation and respiration. The most common gill lesions (discoloration, fraying, clubbing, curling) were consistent with parasite and bacterial infestations. However, fused lamellae and lifting of the epithelium on the lamellae were also seen. Such lesions have been observed in fish exposed to ammonia concentrations of $\geq$ 0.8 mg/L and chronic exposures to copper (Muhvich et al. 1995; Piya et al. 2009; Spencer et al. 2008). Although all NMED (2009) reported ammonia concentrations were well below this level, Buhl (2002) showed that ammonia and copper together at concentrations found in the

Rio Grande could result in chronic toxicity to Rio Grande silvery minnow. Moreover, tilapia exposed to copper at concentrations found at our Rio Grande sites, exhibited similar gill pathologies (Figueiredo-Fernandes et al. 2007).

Hepatocyte appearance can vary depending on season, nutritional status, age, sex, and pollutant exposure (Ferguson 1989). Hepatic glycogen was most often low in all RGSM which may be related to environmental stress or the end of the spawning season, reduced food resources, or a combination of these stressors. Glycogen is used as an immediate energy source when fish are under acute stress. Reduced glycogen may make them lethargic and less able to respond to predators (Smith 1982). Depressed liver glycogen, particularly in summer months, has been related to exposure to heavy metals (Heath 1995; Levesque et al. 2002: Palermo et al. 2008). Aluminum and copper were the only heavy metals that exceeded NM water quality acute or chronic criteria for dissolved levels at site-specific hardness concentrations. However, total water concentrations of copper, aluminum, and iron were highly elevated across sites (Table 5).

Shortened operculum was the gross abnormality observed at the highest frequency. The anomaly has been present since at least 1938. Abnormalities of the opercular complex affect both wild and cultured fish populations. Possible causative factors include, but are not limited to, vitamin-C deficiency or diet (Dabrowski et al. 1988; Grady et al. 1992b; Koumoundouros et al. 1997), exposure to contaminants (Grady et al. 1992b; Lindesjöö et al. 1994; Olsson et al. 1999), turbulence (Al-Harbi 2001; Backiel et al. 1984; Beraldo et al. 2003), and genetics (Beraldo et al. 2003; Koumoundouros et al. 1997; Tave et al. 1983). The cause of shortened opercula in RGSM is not known, but results of our clearing and staining of a few samples suggest the margins of shortened opercula may not have the same bone density as normal opercula. However, this may be due to age differences as the Dexter RGSM were larger and likely older than the Site 2 RGSM. More same-age animals need to be studied. Available

evidence suggests that this deformity may be a non-inherited congenital defect (Tave et al. 1982; Tave and Handwerker 1994), induced during the embryonic or larval stage (Al-Harbi 2001; Koumoundouros et al. 1997). Although the effects of a shortened operculum on fish function, especially at the gills, are unknown, gill pathologies were reported for nearly all fish in this study. Our finding, from analysis of archived samples, that fish with shortened opercula were also shorter in length may further support a negative effect (on growth) of having a shortened operculum.

Gonads presented with few abnormalities. No evidence of effects of estrogenic exposure (e.g., elevated atresia, intersex) was observed in this study. However, the increase in relative proportion of females from upstream to downstream sites, and the possible finding of a male with testicular oocytes warrants further investigation given that the Rio Grande is dominated by wastewater flows much of the year. Moreover, past findings of vitellogenin induction in fish and >20 pharmaceuticals and personal care product chemicals in waste water treatment plant (WWTP) effluents (NMED 2009) indicates that endocrine active compounds are present. The presence of ectopic oocytes needs to be verified with additional samples. Ectopic oocytes are rare but may result during early development from disruption of migration of the primordial germ cells to the gonad (Kobayashi and Hishida 1985).

Temporal

Fish collected in the first year of sampling were larger than the second year suggesting that the first year collections contained larger individuals from a population that may also contain larger fish.

During the summer months (July-October) flows in the silvery minnow critical habitat are greatly reduced, temperatures are high, and wastewater from the three treatment facilities in the study reach comprises a greater volume of the flow (Kelly et al. 2006; NMED 2008b). Resulting salinity, nitrate and phosphate (Zeglin et al. 2006), total organic carbon, and fecal streptococci concentrations (Langman and Nolan 2005) documented to be high during the summer indicate generally reduced water

quality and may cause stressful conditions as reflected by the silvery minnow histopathology observed in this study. July and October measures of total phosphorus and BOD at the sites in this study tended to be higher than during other months (NMED 2009, Table 5). General health as measured by the HAI and SSI indicated a seasonal pattern of greater stress in summer/fall (July/October). Histopathologies also tended to be more prevalent in fish caught in July: more MAs, and fat in livers and spleens; more granulomas in livers; low liver glycogen; larger spleens lower in red blood cells. These results are indicative of general physiological stress and immune system responses. Consistent with these observations, the greatest number of fish with bacteria was collected during July compared to other months (USFWS 2009) and increased leukocyte proliferation was observed during summer. Gill and kidney pathologies were elevated throughout all months and did not show any seasonal trends.

Spatial

In general, fish at the two sites above Albuquerque were healthier than the fish below Albuquerque, however health in fish at all sites was impaired to some degree. Health assessment results reported here were also consistent with Middle Rio Grande water and sediment quality and tissue residue data collected by the New Mexico Environment Department (NMED 2009) during the study period at sites sampled in this study. Although Rio Grande silvery minnows collected at Site 1 were relatively healthier than fish collected at all other sites, water quality exceedences were reported for chronic Al exposure and *E. coli* levels (NMED 2009). Also, carp tissues, only collected at Sites 1-4, were elevated for Zn at Site 1 and not the other three sites (NMED 2009). Naturally elevated Al concentrations are likely in the RGSM critical habitat as the surrounding mountains are rich in aluminum (NMED 2008b). Of the organochlorines tested, only total DDT was at concentrations of concern only at Site 1 and between Sites 2 and 3 (NMED 2009). In the nearly 20 miles downstream to Site 2, effluents from three wastewater treatment plants (WWTPs) and a flood diversion channel for the

city of Albuquerque enter the Rio Grande. Silvery minnow collected at Site 2 were slightly healthier than RGSM further downstream for some metrics but equivalent to downstream fish for others. Water quality exceedences at this site were reported for chronic Al, and *E. coli* as well as for dissolved oxygen and ammonia (NMED 2009). Chronic and acute Cu levels were exceeded in the river reach just upstream of Site 2 (NMED 2009). Sediment semi-volatile PAHs (polyaromatic hydrocarbons) measured at all sites exceeded NOAA/SQuiRT guidelines primarily at Sites 2-4, and were not detectable at Sites 1 and 6 (NMED 2009). Site 3 is the first site geographically below metropolitan Albuquerque. Effluent from the Albuquerque wastewater treatment plant is the major river inflow. At this site or in the river reach above it to Site 2, water quality exceedences were reported for chronic Al and Cu, acute Cu, *E. coli*, dissolved oxygen, and ammonia (NMED 2009). At Site 3, cyanide, as well as PAHs, was elevated in sediments (NMED 2009). Water quality, sediment contaminant levels, and fish tissue residue results were similar at Sites 3 and 4. A couple of smaller WWTPs enter the river in the nearly 20 miles between these latter sites, and a few more are found in the 50 miles between Sites 4 and 5 and Sites 5 and 6. Only the metals and not PAHs, cyanide, ammonia or pH, were of concern at Site 5 and by Site 6 only chronic Al was in exceedence (NMED 2009). The HAI, SSI, and the percentage of fish with two or more pathologies tended to indicate increasing impairment downstream at or below Site 3. The incidence and severity of pathologies was generally low or variable among sampling dates and numbers of fish sampled were low, and this may have prevented significant site-specific associations. However, liver granulomas were common at Sites 3 and 4, spleen granulomas were frequent at Site 6, and MAs tended to be highest at Site 3 and lowest at Site 1. In addition, the immunological response as evaluated by leukocyte production was greater at Site 3 than Site 1.

Our results indicate that the RGSM in the reach of critical habitat between Bernalillo, NM and Bosque del Apache National Wildlife Refuge are experiencing chronic stress as evidenced by a suite of

health indicators. Given the results from the bioindicators used in this study and the stressors measured by the NMED (2009), it appears that the stress is likely related to constituents of poor water and sediment quality (metals, bacteria, and possibly PAHs). Furthermore, the biology of the RGSM as a benthic feeding fish occupying slow moving waters increases its exposure to chemicals and pathogens associated with sediments. Although the present health study was not designed to identify cause and effect linkages, the health effects we observed in the Rio Grande silvery minnow are in agreement and consistent with the known impacts of urban effluents, stormwater runoff, and agricultural return waters. Recently, RGSM was re-introduced to the Rio Grande near Big Bend National Park (http://www.fws.gov/Endangered/home_stories/silvery_minnows.html). Health monitoring of RGSM along with routine population monitoring in this less polluted section of the Rio Grande and comparison of results with the present and future studies in the middle Rio Grande should serve to increase our understanding of the relative impact of contaminated habitats on Rio Grande silvery minnow recovery.

Appendix 5. Rio Grande Silvery Minnow Fish Health Study – Fish Pathogen Assessment

Cover photography (pictures listed left to right and top to bottom) by J. Woodland/USFWS: 1) *Epistylis* sp. on a fish scale, 2) viral cytopathic effect on fathead minnow cells, 3) *Apiosoma* sp. on a gill lamellae, 4) *Gyrodactylus* sp. from a skin scrape, and 5) *Trichodina* sp. from the gills.

Abstract: Assessment of pathogens affecting the Rio Grande silvery minnow *Hybognathus amarus* is crucial in understanding impacts to recovery efforts of this federally listed endangered fish. Viral, bacterial and parasite pathogen examinations were conducted on Rio Grande silvery minnow in this study to provide a comprehensive pathogen assessment. The prevalence of isolated pathogens was determined from up to 60 fish for bacteriology and virology and up to 30 fish for parasitology from each sampling. Collections occurred quarterly at six sites along the middle section of the Rio Grande between July 2006 and July 2008. The top four most prevalent parasites observed were from the family Trichodinidae and the genera *Apiosoma, Cryptobia*, and *Ichthyobodo*. No significant bacteria or viruses targeted nationally by the U.S. Fish and Wildlife Service were isolated. There were also no significant overall differences in the mean parasite prevalence between the sites. Correlations between types of infection indicate a majority of 'parasite only' infections (65%) compared to 'bacteria only' (19%) or 'parasites and bacteria' present (16%). The parasites observed in this study range from being normal ectocommensals to possessing potential for acute pathogenesis and are generally indicators of poor water quality. Longer term study and standardization of parasite examination protocols will provide additional information on occurrence trends and potential impacts of the parasites observed. Results of this study provide a baseline of information on the types of pathogens currently observed with Rio Grande silvery minnow in the middle reach of the Rio Grande.

Introduction/Background

Assessment of pathogen presence in the federally listed endangered Rio Grande silvery minnow *Hybognathus amarus* is important for understanding the species' current health status for conservation efforts. This comprehensive study concentrates on pathogen presence for the RGSM extant to the middle section of the Rio Grande. Traditional targeted pathogen categories used for identifying pathogen presence include viruses, bacteria, and external parasites. Depending on the host species, environmental conditions, and pathogens present, pathogen impacts on fish health varies. Many microbes are ubiquitous in nature and may not impact fish health due to natural immunity. However, if environmental conditions or other stressors compromise the fish's underlying immune function, these ubiquitous microbes can cause disease and mortality. Currently there are no known pathogens that specifically target the Rio Grande silvery minnow.

Observing disease or mortality events in the Rio Grande is difficult due to the hydrology, water operations, and turbidity of the water, obscuring monitoring efforts for these small fish. Consequently, to better understand if pathogens are impacting Rio Grande silvery minnow survival and recruitment it is best to take a proactive approach by conducting pathogen examinations on live fish. Dead fish do not generally have much utility for conducting pathogen examinations for several reasons. First, external parasites exit the host quickly after fish death. Second, viruses are obligate intracellular pathogens and may be degraded unless tissue samples are preserved properly for testing since various cellular lytic cascades are initiated postmortem. Third, bacteria multiply exponentially in dead fish that are no longer capable of mounting

protective immune responses resulting in skewed or biased colony counts using bacteria diagnostic methods.

The primary purpose of the pathogen and parasite surveys described herein is to determine the distribution pattern of specific pathogens and parasites on or in Rio Grande silvery minnows collected in the middle reach (New Mexico portion) of the Rio Grande. This research is one component of an interagency objective to establish a baseline health status of the Rio Grande silvery minnow and the Rio Grande. Additionally, relevant bacterial and viral pathogen survey results will add to the base of knowledge for the U. S. Fish and Wildlife Service's National Wild Fish Health Survey (NWFHS) and will be uploaded to the survey's database website for public access.

Parasitology Methods

Rio Grande silvery minnow, collected primarily by the U. S. Fish and Wildlife Service's New Mexico Ecological Services and New Mexico Fish and Wildlife Conservation Office, were examined for external parasites from six locations along the middle section of the Rio Grande. Collection sites were identified based on their proximity to nearby cities: Site 1, Bernalillo; Site 2, Alameda; Site 3, Los Padillas; Site 4, Los Lunas; Site 5, La Joya; and Site 6, San Antonio. The targeted sample size for external parasite examinations was 30 fish per site per time point.

Parasite examinations were conducted on fish sampled quarterly during each of two field sampling years. The sampling dates were as follows: July 2006, October 2006, January 2007, April 2007, October 2007, January 2008, April 2008, and July 2008. Generally, three sites were sampled each week over the course of two consecutive weeks during each collection month

mentioned above. Prior to parasite examination, live Rio Grande silvery minnow were euthanized by overdose with tricaine methanesulfonate (Finquel; Argent Chemical Laboratories, Inc., Redmond, WA). Examination of external parasites was conducted by microscopic examination of wet mounts from skin scrapes and gill clippings from each fish. Skin scrapes were produced by collecting mucus on a cover glass along one side of the fish and then placing the mucus on microscope slides with a drop of distilled water and coverslipping. Gill clips were collected with necropsy scissors and placed on slides similar to skin scrapes. Wet mounts of the skin scrapes and gill clippings were examined at 40x, 100x, 200x, and 400x magnifications using a compound light microscope.

Parasites were identified and enumerated for each of the samples. The number of parasites recorded varied, in part due to the lack of a standardized sampling protocol. Before April 2008 several parasite counts were estimated by collectors. A plus sign was added to indicate additional parasites present than counted and also to estimate a general number of parasites present. After April 2008 each type of parasite was counted up to one hundred. If there were more than 100 parasites present for each parasite type, it was noted with a plus sign (Appendix 5A).

Parasites examined with the compound light microscope were identified to the species level when possible. If parasites could not be identified to species level, the taxonomic family, class and/or genus was recorded. Any visual implant elastomer (VIE) tags present were also recorded based on their color and location. VIE marked fish are captive reared produced fish stocked into the river.

Bacteriology Methods

Samples for bacteriology were aseptically collected from the kidney tissue of each fish with sterile 1-µL inoculation loops (Thermo Fisher Scientific, Rochester, NY). Up to 60 fish per site were sampled for bacteria (Table 1). Tissue samples were streaked onto brain heart infusion agar (BHIA) slants (Becton Dickinson, Sparks, MD) and incubated at 20°C in an ambient air incubator. Individual bacterial colonies that grew in culture within four days were further processed for identification.

Identification of bacteria was conducted following procedures used in sampling and screening of targeted bacterial pathogens described by the Standard Procedures for Aquatic Animal Health Inspections (USFWS and AFS-FHS 2005). The bacteria information recorded follows several assumptions in determining if isolates of bacteria were different (Appendix 5B). In addition to the initial tests of cytochrome oxidase, motility and gram stain or KOH testing, biochemical identification of Gram negative bacteria was conducted using the API 20E™ identification system (bioMérieux® SA, Marcy I'Etolle, France). Bacterial identifications based upon lab results and lab codes (assigned to each culture for tracking back to the individual fish) were recorded (Appendix 5C). Isolates of bacteria identified as targeted pathogens by API, as listed by U.S. Fish and Wildlife Service's Aquatic Animal Health Policy (Part 713 FWS 1 Exhibit 2), were compared to API codes of known targeted pathogens and further tested by direct fluorescence antibody test (DFAT) following protocols listed in Standard Procedures for Aquatic Animal Health Inspections (USFWS and AFS-FHS 2005).

Virology Methods

Whole viscera samples including the kidney were sampled for viral testing. Up to 60 fish per site were sampled (Table 1). Samples of viscera were pooled into groups of five fish pools and diluted 1:10 in Hank's Balanced Salt Solution (HBSS) (Invitrogen, Carlsbad, CA). The HBSS contained the following supplements (all obtained from Invitrogen): penicillin (600 IU per mL), streptomycin (1600 µg per mL), amphotericin B (40 µg per mL) and sodium bicarbonate (375 µg per mL) (HBSS anti-inc medium). Samples were maintained at 4ºC no longer than 72 hours prior to processing *in vitro* at the Dexter Fish Health Unit.

Two methods were used to process the samples *in vitro*. Samples were diluted to a final concentration of 1:100 in HBSS anti-inc medium and either filtered through a sterile 0.45 µm membrane (Pall Corporation, Ann Arbor, MI) or centrifuged (Eppendorf Centrifuge 5810R, Brinkman Instruments Inc., Westbury, NY) to pellet sample debris at 2500 x *g* for 15 minutes. This filtration method allowed for quicker processing of the samples on the same day by physically removing non-viral particles from the sample. Centrifugation of the samples was performed after a two hour incubation at 15ºC or overnight incubation at 4ºC and this method allowed for additional antibiotic disinfection of the sample prior to inoculation of tissue cultures.

In general, sample processing and testing was conducted following procedures described by the Standard Procedures for Aquatic Animal Health Inspections (USFWS and AFS-FHS 2005). However, since the samples from this study originated from the wild, our test had some slight modifications in virology procedures. These procedures followed the USFWS National Wild Fish Health Survey laboratory manual which does not require conducting blind passes for cell culture and the observation period for virus isolation is 21 days. The other exception was the

time period between collection of the samples and processing samples *in vitro* for virology. This time period varied with the day the samples were collected from all sites for the week and return of the samples for *in vitro* processing at the end of the week.

Fat head minnow (FHM) and chinook salmon embryo (CHSE-214) cells were used for virus isolations. Cultures in 24 well cell plates (Becton Dickinson, Franklin Lakes, NJ) were inoculated in duplicate, excluding negative (no inoculum) controls, and incubated at 25ºC for FHM cultures and 15ºC for CHSE-214 cultures. After inoculation, cells were rocked at the appropriate incubation temperature (25ºC for FHM, 15ºC for CHSE-214) for 45 minutes to facilitate viral particle attachment and then overlaid with 1 mL of Eagle's Minimum Essential Medium (EMEM; Invitrogen) supplemented with 5% fetal bovine serum (Thermo Fisher Scientific, Logan, UT), penicillin 100 IU/mL, streptomycin 100 µg/mL, amphotericin B solution 2.5 µg/mL, 15 mM HEPES and sodium bicarbonate 2.2 mg /mL (pH 7.2) for each well. Samples were monitored and observations recorded at least biweekly for viral cytopathic effect (CPE) during the incubation period of the test.

Any samples with observed CPE were tested by polymerase chain reaction (PCR) assay for largemouth bass virus (LMBV) and reverse-transcriptase PCR (RT-PCR) for infectious pancreatic necrosis virus (IPNV). LMBV and IPNV were the only suspected viruses for this environment that were also considered listed pathogens as determined by U.S. Fish and Wildlife Service's Aquatic Animal Health Policy (Part 713 FWS 1 Exhibit 2). DNA extraction for LMBV was conducted using the BuccalAmp DNA extraction kit (Epicentre Biotechnologies, Madison, WI) per established laboratory procedures along with the manufacturer's directions with the kit. PCR for LMBV was conducted as described in the National Wild Fish Health Survey Laboratory Procedures Manual. Extractions of RNA for IPNV were conducted using a

QIAamp® MinuElute® Virus Spin Kit (QIAGEN Inc. - USA, Valencia, CA). The RT-PCR for IPNV was conducted as described by the Standard Procedures for Aquatic Animal Health Inspections (USFWS and AFS-FHS 2005). PCR reactions were run on 1.5% agarose gels in tris-acetate-EDTA buffer and stained with ethidium bromide and compared with a 1 Kb DNA ladder (Invitrogen) to estimate amplicon size.

Data Treatment and Statistical Analysis

Parasite prevalence was determined from the mean and median observations from all sampling periods and sites. The most dominant parasite prevalence between each site for the entire study was then compared. The mean plus and minus the standard error of the mean (± s.e.m.) was used to compare differences in the overall prevalence of infection for selected parasites between sites. The statistical analysis of differences observed between sites for each type of parasite, based on the mean ± s.e.m., was considered statistically significant by *t*-test when the *P* value was < 0.05.

Correlations were determined between three levels of observations, including identifying both bacteria and parasites on the same fish, identifying parasites only on a fish or bacteria only on fish. The percentage of each type of correlation mentioned above from each location and sampling period was then determined. The results of this correlative analysis are then compared to provide an overall summary.

Results

Four external parasite types (taxonomic family or genera) were dominant in the external parasite examinations (Figures 1 and 2). In order of greatest to least prevalence, these were identified as Trichodonidae, *Apiosoma* sp., *Cryptobia* sp. and *Ichthyobodo necator*. Additional parasites observed in the study and identified in order of greatest to least prevalence included: Monogenea (primarily *Gyrodactylus* spp.), *Epistylis* sp., *Ambiphrya* sp., *Lernaea cyprinacea* (anchor worm), *Icthyophthirius multifiliis* ("Ich"), *Clinostomum marginatum* (yellow grub), *Trichophrya piscium*, and *Chilodonella cyprini*.

No significant differences were observed between sample sites for the top four most prevalent parasites ($P > 0.05$). Significant differences tested were based on the observable differences between the mean ± s.e.m. (Table 2).

Comparison between bacterial and parasite isolations observed did not reveal any discernable patterns from the data collected for the individual sites at different collection time points (Table 3). Fish from Site #6 San Antonio did show consistent parasite infestations but there was no data collected from this site during October 2006 and April 2007; therefore, no statistical significance to this observation could be determined (Table 3). When considering the majority of types of infections with bacteria or pathogenic parasite isolations per sampling period, 65% of the sampling periods resulted in a majority of 'parasite only' isolations from fish while the remaining sampling periods resulted in a majority with both 'parasites and bacteria' 16% of the time and 19% of the time with 'bacteria only'. Table 4 describes the percentage observed with parasites and bacteria for each site and collection. The overall mean prevalence of pathogenic parasite infestations compared to bacterial isolations was 70% and 37%, respectively,

for the entire study when averaging each site's data. The San Antonio site had the greatest prevalence of parasite infestations at 78% followed by Los Lunas at 72%, Los Padillas and La Joya at 69%, Alameda at 67% and Bernalillo at 66%. The La Joya site had the greatest prevalence of bacterial isolations (44%), followed by Bernalillo at 41%, Los Padillas and Los Lunas at 40%, Alameda at 34% and San Antonio at 22%.

No bacteria or viruses isolated from this study were considered targeted fish pathogens per the USFWS Aquatic Animal Health Policy (Part 713 FW 1 - Exhibit 2). Of the bacteria identified by the API test, 33 different genera of Gram negative bacteria were represented. One isolate was presumptively identified by API as *Aeromonas salmonicida*, a targeted bacterial pathogen, but later determined as negative by a direct fluorescent antibody test more sensitive and specific for *A. salmonicida*. Several Gram positive bacteria, not characterized by API, were isolated from the Rio Grande silvery minnows. One unidentified virus was isolated from one pool out of twelve collected in October 2007 at the Los Lunas sampling site. This sample was confirmed negative for LMBV and IPNV when tested by PCR. A sample of this virus was identified as a putative Aquareovirus based on its cytopathic effect in culture (J. Winton, U.S. Geological Survey–Western Fisheries Research Center, Seattle, WA, USA, personal communication). Having been characterized as a non-targeted pathogen, no additional identification of the virus was attempted.

Discussion

Potential pathogen trends were examined in this study to provide a baseline of knowledge in determining possible health concerns for the Rio Grande silvery minnow. This study

examined the specific areas of parasitology, virology, and bacteriology in determining pathogenic trends. Isolation of individual parasites, viruses and/or bacteria does not always indicate a health concern as all organisms, including fish, harbor normal microflora and commensal parasites. Therefore, the significance of microbes isolated in this study are discussed in context of detailing potential impacts for causing disease or mortality and by providing possible explanations for their isolation based on their prevalence in specific sites.

Most external parasites observed in this study are ubiquitous and are expected to be found in low numbers in free ranging fish populations (Beverly-Burton 1994, Ewing 2002, Taylor and Goodwin 2002). In culture conditions these parasites can rapidly multiply and transmit to other fish with crowded conditions, causing disease. In hatchery conditions, water flow and exchange may also be reduced which can allow potential fish pathogens to persist and infect fish. In the wild, fish have greater capability to flee undesirable environments that may lead to pathogen infestation. As the health of a fish is compromised by increases in parasite burden the potential for pathogenesis is also increased. The degree of parasite infestation should then be the primary area of interest when determining whether parasites are having a negative impact on an individual fish's health (Taylor and Goodwin 2002).

However, because our data collection lacked a standardized approach for counting numbers of parasites, selection of gills for examination and the area of observation, the most accurate use of the data was to determine parasite prevalence. Although parasites observed were counted, sample collection counts of parasites may not accurately reflect the degree of infestation uniformly.

The prevalent Trichodinids, *Apiosoma* sp., *Cryptobia* sp., and *I. necator* parasites isolated from this study can all be found on the skin and gills of fish (Hoffman 1999, Mitchum 1995,

Noga 2000). *Cryptobia* completes its life cycle on the gills and is generally only found on the skin in heavier infestations (Hoffman 1999, Mitchum 1995). Of the four most prevalent parasites, *Apiosoma* and *Cryptobia* are primarily ectocommensal organisms while the Trichodinids and *I. necator* are considered ectoparasitic (Hoffman 1999, Mitchum 1995, Noga 2000).

The sessile ectocommensals isolated in this study, including *Epistylis* and *Ambiphrya*, primarily derive their nutrients from the water as bacteriovores and by filter-feeding organic debris (Noga 2000). Isolation of these ciliated parasites is typically an indicator of organically polluted waters that may also have high loads of bacteria (Noga 2000). They only become a problem for fish when their numbers increase, leading to a physical impediment to gas exchange required for respiration (Hoffman 1999, Mitchum 1995, Noga 2000). Reduced respiration then contributes to mortality of fish. Like the ectocommensal organisms, infestations with *I. necator* and *Chilodonella* are more likely when environmental conditions such as poor water quality are present (Mitchum 1995, Noga 2000).

The ectoparasites isolated from this study, including the prevalent Trichodinids and *I. necator* plus the less prevalent *Chilodonella*, Monogenea (specifically the viviporous *Gyrodactylus* spp.), *L. cyprinacea*, *I. multifiliis,* and the digenean *C. marginatum,* are primarily pathogenic in fish (Hoffman 1999, Mitchum 1995, Noga 2000). In fact *L. cyprinacea*, *I. multifiliis*, and *C. marginatum* require fish to complete their life cycle and can amplify rapidly in closed systems. Even though *Chilodonella*, Monogenea, *L. cyprinaea*, and *I. multifiliis* are very destructive fish parasites, they were not very prevalent in the sites sampled. The numbers observed in this study did not indicate these parasites were problematic for the Rio Grande silvery minnow. However, *Lernaea* does have potential to cause mortality with only one

individual if the infected fish is small (Noga 2000, Roberts 1978). Conversely fish can tolerate a high burden of metacercaria infestation, with the exception of heavy acute infections in small fish such as the *C. marginatum* (yellow grub) isolated in this study (Noga 2000).

Ichthyobodo necator, formerly classified as *Costia necatrix*, is perhaps one of the most important and most destructive external parasites identified. This parasite causes high and acute mortality due to its parasitism of epithelial cells of fish (Markevitch 1963, Noga 2000). Environmental conditions conducive to *I. necator* reproduction lead to rapid amplification that may eventually spread externally over the entire fish (Mitchum 1995, Noga 2000). While the parasite may colonize the epithelium without much visible pathogenesis in healthy fish, *I. necator* typically becomes a problem for warm water species in cooler water conditions when their immune function may be diminished (Egusa 1991, Noga 2000). The parasite cannot survive in temperatures above 30ºC and prefers water temperatures below 25ºC (Noga 2000). As Mitchum (1995) reported previously, *Cryptobia* infestations are often associated with *Ichthyobodo* infections in the same fish, contributing to increased pathogenesis.

In contrast with *Ichthyobodo*'s potential for acute mortality, the prevalent Trichodinids isolated in this study often lead to chronic mortality in fish, with a potential of 1% loss per week (Noga 2000). This percentage may increase with concomitant secondary bacterial infections (Noga 2000), something that often occurs with ectoparasite infections and further contributes to damage of the mucus and epidermal layers. Some species of Trichodinids are highly pathogenic and can rapidly cover the entire fish leading to death (Hoffman 1999). In fact Noga (2000) states that *Apiosoma* actually acts as a nidus for bacterial colonization.

The bacteria isolated in this study are likely secondary pathogens or possibly environmental bacteria that contaminated the kidney during sampling in the field. No bacteria

isolated during this study were targeted pathogens as listed by the USFWS Aquatic Animal Health Policy (Part 713 FWS 1 Exhibit 2).

The cell lines used for isolating viruses are capable of isolating more than targeted primary viral pathogens as listed by the USFWS Aquatic Animal Health Policy (Part 713 FWS 1 Exhibit 2). The selection of cells for this study were based on their ability to support the growth of viruses of concern from warm and coldwater fish species in the southwest region of the United States. The targeted viruses for this study included: LMBV, IPNV, *Oncorhynchus masou* virus, and Infectious Hematopoietic Necrosis Virus. Only one virus, a putative Aquareovirus, was isolated in this study. Unlike many bacterial pathogens that will grow in non-selective culture media, viruses are often host specific and must be cultured in permissive cell lines. The one virus isolated in this study is not considered a disease causing agent and is among many other viruses grouped into the Aquareoviridae that have been isolated from free-ranging fish.

Recommendations for Future Work

Longer term monitoring is advisable to determine trends in the overall health of the Rio Grande silvery minnow in the middle section of the Rio Grande. This current study provides a baseline of health information that can be used to compare to health and population trends for the Rio Grande silvery minnow in the future and highlights deficiencies in current sampling methods that will allow for refinement in future studies. Development of a standardized parasitology sampling protocol should provide more robust determination of the degree of infection for future studies. Enumeration of the degree of infection will provide a better determination of the impact parasites are having on the Rio Grande silvery minnows. Testing should be expanded to

incorporate methods that target specific bacterial pathogens in fish and decrease the effort and expense entailed to identify bacterial isolates that are environmental microflora and not detrimental to fish health.

Drought and environmental contamination from increasing urbanization are likely to put continued strains on Rio Grande silvery minnow populations in this region. Establishing a relevant fish health baseline and continued monitoring of fish health parameters for this species is critical to understanding impacts to recovery efforts of this federally listed endangered fish.

55 fish total. (Due to miscount in field initial count was thought to be 93 for both histo and fish health)

Virology and Bacteriology were taken first for a total of 55 fish. Only 25 fish were examined for parasites.

Gills appeared to be in over all good condition. Light to moderate mucous.

Notes: 17 fish collected.

*=picture (*)=video

All fish examined had excess mucous on the gill and they were also clubbed. All fish except #1, 4, 9, and 13 were gravid.

Fish #41 to 45 no good, not used for viral or bacterial samples, or parasites except the one Lernaea.

Fish 1 to 40 sampled for external parasites, bacteria, viruses.

DOA = dead on arrival.

Appendix 5B. Assumptions for Determining Bacterial Identification when Several Isolates of Bacteria were Isolated from the Same Fish.

A) If different isolates from the same fish had identical motilities, CO test results and the bacteria were gram positive, it was assumed that they were identical bacteria without further testing.

Reason: There were no other tests performed for identifying gram positive bacteria to the genus or species level.

B) If isolates from the same fish were identical in CO, motility, and API results, these bacteria were considered the same.

Reason: No other tests were performed to make a valid argument that the bacteria were different. It is possible to pick bacteria growing on agar in Petri dishes that look different but are really the same bacteria. Sometimes colonies may appear different due to the amount of growth variance between colonies.

C) If the API codes were not exactly identical, even in cases where the API codes were off by one number, the bacteria were considered different.

D) If CO and motility were the same and later the bacteria were lost (died) or the growth was very slow (3–4 days before seeing any appreciable growth) and no API tests were performed from several isolates on the same fish, these bacteria isolates were considered different bacteria.

Reason: Samples may appear to be the same based on CO and motility, but several bacteria can share these same results and be different bacteria. Without further testing, it is not possible to determine if these bacteria were the same or identical. The assumption is to fall back on the identification of the bacteria as different based on the morphology of the bacterial colonies on the BHI agar plates.

E) If API codes were identical but the motility was different, these bacteria were considered the same.

Reason: Observations of motility can be dependent on how old the bacteria were when examined. Sometimes you may only observe motility in small numbers; therefore, it is possible to miss it at times due to human error. The API codes are not always as subjective as the motility tests.

F) If isolates from the same fish included bacteria with the same CO, motility and gram stain test results and no API was performed, then it was determined that not enough information was available to report the number of different isolates. These samples were not taken into consideration for statistics. Statistics not reported in the body of this paper included the average number of different bacteria, minimum number of different bacteria, and maximum number of different bacteria on the fish per sampling event. A sampling event is defined by the site location and the date it is sampled.

COMMENTS: Rio Grande silvery minnow. CO, & KOH test on 10-19-6 from 24hr old growth. TSB on 10/26/06. ***API suggested small possibility that bacteria may be Aeromonas salmonicida ssp salmonicida, but further testing ruled out possibility.

Collaborative Research and Monitoring: Evaluation of the Rio Grande Silvery Minnow Health in Relation to Changes in Water Quality, Pathogens and Other Environmental Stressors:

Multi-locus Major Histocompatibility Complex Class IIβ and Parasite Diversity in the Rio Grande Silvery Minnow.

Executive Summary

Long-term persistence of species depends partially on avoiding loss of genetic variation (Hedrick *et al.* 1996). This variation forms the basis of a species' ability to adapt and respond to changing environments. For example, genetic variation of genes involved with immunity serves as the foundation of an individual's response to disease pressures. Variation at immune genes is especially important for aquatic species, whose chemical and microbial environment is impacted heavily by humans, which may increase their risk of exposure to pathogens (De Swart et al. 1996; Harvell et al. 1999). In this portion of the fish health study we characterized and measured diversity at genes of the major histocompatibility complex (MHC) Class IIβ in the Rio Grande silvery minnow, *Hybognathus amarus*. These data were used to examine the relationship between MHC variation and pathogen diversity. Major findings of this study were:

- Seventy-two different MHC alleles were identified based on MHC Class IIβ Exon two cDNA sequences and all alleles shared conserved features of classical MHC Class IIβ.

- Three divergent groups of alleles were identified on the basis of phylogenetic analysis.

- The expression of Hyam-DAB1*05 was associated with lighter *Costia* spp. infection whilst expression of Hyam-DAB2*06 was associated with heavier *Costia* spp. infection. Expression of Hyam-DAB1*13 was associated with heavier *Apiosoma* infection. No relationship was detected between presence or absence of Hyam-DAB1*03 or Hyam-DAB2*04 an infection with particular species.

- No association between gill parasite diversity (number of species per individual) or abundance and MHC diversity (number of MHC alleles per fish) was detected.

- No association was detected between pathogen diversity or abundance and the number of MHC allelic groups expressed by individuals.

- Parasite and bacterial species diversity and abundance also differed spatially.

Introduction

It is widely recognized that there is a relationship between levels of genetic diversity and a species' ability to respond to changing environmental conditions such as exposure to novel pathogens (e.g. Reed and Frankham 2003) and that there can be a negative relationship between the probability of extinction and the amount of genetic variation (Saccheri et al. 1998; Westemeier et al. 1998). In small populations, extinction risk may be heightened if individuals lack the diversity necessary to face infections from metazoan parasitic, bacterial and viral infections. In degraded environments, particularly aquatic ones, endangered species may be confined to areas (such as isolated pools) where they are more susceptible to infection. A case in point is the Rio Grande silvery minnow, a federally endangered North American cyprinid that now occupies a a fraction of its historic range in the Rio Grande, New Mexico. The Rio Grande is a modified and highly impacted river system. From spring to fall, river flows are largely diverted to supply agricultural lands and to meet interstate water delivery obligations. This can cause parts of the Rio Grande to be intermittent and, as a consequence, fish can become confined to pools. Under these conditions, fish are exposed to degraded water quality (e.g. increased temperatures and decreased dissolved oxygen) and increased competition and predation. High fish densities can increase the probability of exposure to pathogens and exacerbate susceptibility to infection due to stress. To date we have tracked overall measures of genetic diversity in Rio Grande silvery minnow including allelic richness, heterozygosity and genetic effective size (Alò & Turner 2005; Turner et al. 2006; Turner & Osborne 2006). The markers used to track these parameters are presumably neutral (i.e. not under selection). Although these neutral markers provide crucial information about demography, genetic effective size, and stocking practices, they do not allow us to make specific predictions about whether the species maintains the genetic diversity needed to respond to disease pressures. This study aims to address these concerns by examining genes of the major histocompatibility complex (MHC), a critical component of the adaptive immune response in vertebrates (e.g. Klein 1986).

Major histocompatibility complex genes encode receptor molecules that recognize and bind foreign peptides, which are then presented to immune cells, initiating an immune response. MHC comprises two subgroups that are involved with immune function: i) Class I molecules that are expressed on the surface of nucleated cells and

are responsible for defense against intracellular pathogens including viruses; and ii) Class II molecules that occur on antigen-presenting cells and are involved with defense against extra-cellular pathogens such as bacteria, arthropods and helminths. Nucleotide sequence variation within the peptide binding region of MHC is directly related to the individual's ability to mount an immune response to specific suites of pathogens (e.g. Davenport & Hill 1996; Hill 2001). Hence, MHC is highly polymorphic, containing the most variable genes described in vertebrates. This variation may also be a product of the role that MHC appears to play in mate choice in some species (e.g. Landry & Bernatchez 2001; Milinski. 2006; Penn & Potts 1999). One of the most important distinctions between the MHC genes in bony fish and other vertebrates, is that the two classes of MHC genes are found on separate chromosomes in bony fish (Bingulac-Popvic et al. 1997; Sato et al. 2000).

Diversity at MHC is thought to be maintained by over-dominant or frequency-dependent selection (forms of balancing selection). Over-dominant selection describes the case whereby the heterozygous condition at a locus is advantageous. In the case of MHC, having multiple alleles at a locus may allow an immune response to be mounted against different suites of pathogens. Frequency-dependent selection is a dynamic process whereby the relative fitness of an allele varies depending upon its frequency within the population. Variation can also be maintained by diversifying selection, whereby genotypes that depart from the average condition in either direction are favored. In some fish, like brown trout, particular MHC alleles may confer resistance to particular pathogens (e.g. Langefors et al. 2001; Paterson et al. 1998). There are also cases where an MHC allele causes susceptibility to a disease (reviewed in Apanius et al. 1997). In other fish, overall heterozygosity at MHC is related to survivorship from infection (Hedrick et al. 2001a; Arkush et al. 2002, Wegner et al. 2003). There is also evidence that parasites drive MHC variability; however, evidence also suggests that there is an optimal number of MHC alleles within individuals (e.g. Wegner et al. 2003).

MHC sequences have been characterized to varying degrees in bony fishes. These include various trout and salmon, pufferfish, sticklebacks, cichlids and several representatives of the fish family Cyprinidae including common carp (*Cyprinus carpio*) (Ono *et al.* 1993; van Erp *et al.* 1996), zebrafish (*Danio rerio*) (Ono *et al.* 1992, Sültmann *et al.* 1993; Sültmann *et al.* 1994) and barbs (*Barbus intermedius* complex) (Dixon *et al.*

1996; Kruiswijk *et al.* 2004). More recently, complementary DNA[1] (cDNA) sequences have been obtained from additional cyprinids including several representatives of the subfamilies Cypininae, Gobioninae, Tincinae and Leucisinae (Ottova *et al.* 2005). These studies have provided crucial insight into the organization of the MHC regions in the Cyprinidae, the largest family of freshwater fishes in the world (~2400 species). A major finding of these studies was the identification of two groups of divergent alleles (DAB1 and DAB3) but it is not clear how many loci these represent.

Although there are around 270 endemic North America cyprinids, there have been no descriptions or published studies of their MHC genes. Despite the large number of species worldwide, fewer than five population-level studies have been published that considered MHC genes within this group of fishes. Population studies have been conducted in the Lake Tana African 'large' barb (*Barbus intermedius*) species flock (Kruiswijk et al. 2005) and in carp bream (*Abramis brama*) (Ottova et al. 2007). The latter study is the first (to our knowledge) that simultaneously considered the correlation between diversity at two transcribed MHC allelic groups and parasite load, parasite diversity, immuno-competence, condition factor and sexual ornamentation. Major finding of their study included: i) identification of two different allelic groups (DAB1 and DAB3) that were under different selective regimes; ii) transcription by individuals of alleles from one, or both allelic groups; iii) a high level of diversity at MHC (in 20 individuals examined 32 transcribed MHC alleles were identified); iv) no association between presence of parasite species and particular alleles; v) correlation between transcription of two DAB1 alleles with increased parasite abundance and vi) individual nucleotide diversity at either DAB1 or DAB3 increased with abundance of two parasite species.

This study aimed to characterize and measure diversity at MHC Class IIβ in the Rio Grande silvery minnow, *Hybognathus amarus*, and to examine the relationship between this variation and pathogen diversity. Three specific questions were addressed:

i) Is there an association between specific MHC alleles and prevalence and intensity of infection by pathogens?

ii) Does increased diversity at MHC confer protection from disease outbreaks?

[1] *Complementary DNA is DNA synthesized from messenger RNA in a reaction facilitated by the enzyme reverse transcriptase. cDNA sequences include exons (sequences that code for functional genes) but not introns (sequences between genes) or non-functional genes.*

iii) Is individual MHC diversity correlated with parasite species or abundance?

Methods

Sample Collection

Genetic analysis was conducted on samples collected during July fish health monitoring July 18th-July 27th 2006 and July 8th – 15th 2008. Fish were euthanized with an overdose of MS-222 (tricaine methanesulphonate). A small piece of caudal fin was removed after each fish was examined for parasites. Fin clips were preserved in 95% ethanol. Whole fish sampled for parasites were frozen and deposited at the Museum of Southwestern Biology Division of Fishes. Genomic DNA was isolated from 30 individuals per locality for genetic analysis. In addition, gill tissue was collected from the first 20 individuals examined for parasitic infections from each collection locality in 2006. In 2008 gill tissue was taken from 30 individuals. Gill tissue was preserved in RNA*later*® (Ambion) for characterization and analysis of cDNA and stored at -20°C to -80°C. Total nucleic acids, including genomic DNA and mitochondrial DNA (mtDNA) were extracted from air-dried fin clips using proteinase-K digestion and organic extraction methods (Hillis *et al.* 1996).

Microsatellites

Individuals were genotyped at seven polymorphic microsatellite loci: *Lco1*, *Lco3*, *Lco8* (Turner *et al.* 2004), *Ca6* and *Ca8* (Dimsoski *et al.* 2000), and *Ppro118* and *Ppro126* (Bessert & Orti 2003). The following pairs of loci were amplified using multiplex PCR: *Lco1*/ *Ca6*, *Lco3* and *Lco8* (1X PCR buffer, 2 mM MgCl2, 125µM dNTPs, 0.40-0.50 µM each primer, 0.375 units TAQ) and *Ppro118*/*Ppro126* (1X PCR buffer, 3 mM MgCl2, 125µM dNTPs, 0.40-0.50 µM each primer, 0.375 units TAQ). *Ca8* was amplified alone (1X PCR buffer, 3 mM MgCl2, 125 µM dNTPs, 0.50 µM each primer, 0.375 units TAQ polymerase). PCR cycling conditions for all loci were: one denaturation cycle of 94°C for 2 mins followed by 30 cycles of 94°C for 20s, 50°C for 20s, 72°C for 30s. For *Ppro 118*/*Ppro126* cycling conditions were one denaturation cycle of 94°C for 2 mins followed by 30 cycles of 94 °C for 20s, 60°C for 20s, 72°C for 30s. Primer concentrations in multiplex reactions were varied to facilitate equal amplification of both loci. Prior to electrophoresis 1.2µl of PCR product was mixed with 1.2µl of a solution comprised of formamide (62.5%), ABI ROX350 size standard (12.5%) and loading buffer (25%) and

denatured at 93°C for 2 minutes. Samples were run on an ABI 377 automated DNA sequencer at 50°C for 2.5 hours. *Ppro 118*/*Ppro126* and *Ca8* PCR products were run on an ABI 3100 automated capillary sequencer. One microliter of PCR product was mixed with 10µl of formamide and 0.3µl of HD400 size standard and denatured at 93°C for 5 minutes prior to loading. Genotype data was obtained using Genemapper Version 4.0 and Genescan 3.1 (Applied Biosystems).

Mitochondrial DNA- ND4

Individuals were screened for variation in a 295 base pair fragment of the mitochondrial ND4 gene using single stranded conformational polymorphism (SSCP) analysis and DNA sequencing as described in Alò and Turner (2005).

MHC- RNA Isolation and cDNA Synthesis

RNA isolations were conducted using Trizol Reagent (Invitrogen). Gill tissues were placed in 1.5 ml eppendorf tubes with 1 ml of Trizol and pulverized using a plastic pestle. Isolations were completed according to the manufacture's instructions. cDNA (complementary DNA) was synthesized from RNA using Qiagen Omniscript® or Sensiscript® Reverse Transcription kits following the manufacturer's instructions.

Primer Design

Primers that amplified MHC Class IIβ exon 3 were designed by comparing published sequences of the zebrafish and common carp (van Erp *et al.* 1996). The light strand primer (MHC2-3) was located at the beginning of exon 3 and the heavy strand primer (MHC2-4) (Table 1) was located at the beginning of exon 4. These primers amplify a fragment that encompasses exon 3, intron 3 and partial exon 4 (data not presented). Using the sequences obtained with these primers, locus specific primers were designed to amplify partial exon 3 and partial exon 2 when used in combination with previously published FishC12S (Ottova *et al.* 2005). To obtain sequences from the five prime end of Rio Grande silvery minnow exon two, a primer was designed in the leader peptide by comparing zebrafish and common carp (van Erp *et al.* 1996) sequences (*Ex2F*). Used in combination with *MHC2-4*, sequences were obtained for entire exon 2 allowing the design of primers that amplified this exon. A 3' primer was also designed based on Rio Grande silvery minnow sequences that would amplify exon 2 regardless of which allelic group was present in the individual.

Allele screening

Individual cDNA samples were screened for the presence of each allelic group using group specific primer combinations. DAB1 alleles were amplified (1X Genescript Taq polymerase buffer, 3mM $MgCl_2$, 125µM dNTPs, 0.35µM each primer [*MHC Ex2F* and *Lc1R*], 0.375 units Taq polymerase) under the following PCR cycling parameters: one denaturation cycle of 92°C for 2 mins followed by 30 cycles of 90 °C for 20s, 53°C for 20s, 72°C for 20s and a final extension step of 72°C for 10 minutes. DAB1(2) alleles (see results) were amplified (1X Genescript Taq polymerase buffer, 3mM $MgCl_2$, 125µM dNTPs, 0.35µM each primer [*MHC Ex2F* and *Lc2R*], 0.375 units Taq polymerase) under the following PCR cycling parameters: one denaturation cycle of 92°C for 2 mins followed by 30 cycles of 90 °C for 20s, 56°C for 20s, 72°C for 20s and a final extension step of 72°C for 10 minutes. DAB3 alleles were amplified (1X Genescript Taq polymerase buffer, 3mM $MgCl_2$, 125µM dNTPs, 0.35µM each primer [M*HC Lc4F* and *Lc4R*] 0.375 units Taq polymerase) under the following PCR cycling parameters: one denaturation cycle of 92°C for 2 mins followed by 30 cycles of 90 °C for 20s, 58°C for 20s, 72°C for 20s and a final extension step of 72°C for 10 minutes. For individuals that failed to amplify using the primer combination given above, *MHC Ex2F* or *MHC Lc4F* was used in conjunction with MHC-Ex3R (1X Genescript Taq polymerase buffer, 3mM $MgCl_2$, 125µM dNTPs, 0.35µM each primer, 0.375 units Taq polymerase). Screening reactions were conducted in 10µL volumes.

Single Stranded Conformational Analysis

Samples that were positive for each of the allelic groups were then amplified in 15µL volumes (using the above conditions). Five microliters were used to check for successful PCR amplification and 10µL of sequencing stop solution (95% formamide, 20 mM EDTA, 0.05% bromphenol blue, 0.05% xylene cyanol FF) was added to the remaining 10µL of PCR product. Samples were denatured at 93°C for 5 minutes and immediately quenched on ice. Fifteen microliters of each sample were loaded on a non-denaturing polyacrylamide minigel (5% acrylamide for allelic groups DAB1(2) and DAB3 and 6% for DAB1) (with 50% glycerol). Samples of known haplotype were included to assist in haplotype designation for unknown samples. Electrophoresis was carried out on a BioRad minigel system (Protean® II xi Cell) in 1X TBE at approximately 4°C for 4 hours

for DAB1(2) and 4.5 hours for groups DAB1 and DAB3. Gels were stained in ethidium bromide and visualized on a UV transilluminator.

Gel plugs were removed from the gel using a razorblade from each variant on the gel. Gel plugs were resuspended in 30µl of deionized water and 30µl of TE and incubated at 37°C shaking for 2-3 hours. Samples were then centrifuged for 20 minutes at 30,000 RPM and the supernatant removed and placed in a new 1.7 ml centrifuge tube. 500 µL of 100% ethanol was added and the tube then placed at -80°C for 15 minutes to precipitate the DNA. Samples were centrifuged for 20 mins at 30,000 RPM to pellet the DNA. The pellet was dried at room temperature and then resuspended in 50µL of TLE. One microliter of this was used in PCR reactions using conditions listed above. PCR products were purified using Marligen PCR cleanup kit and sequenced using ABI Big Dye Terminator kit V. 1.1. Sequencing was conducted on an ABI Prism 3130 capillary sequencer (Applied Biosystems). Sequences were visualized and checked using Sequencher Version 4.6 (Gene Codes Corp).

Cloning

For individuals that appeared to be heterozygotes (and for a portion of homozygotes) PCR products were cloned using the Promega pGEM-T Easy Vector kit following the manufacturer's directions. Plasmid DNA was purified using a boil preparation method (Sambrook *et al.* 1989). Between four and eight clones were sequenced per individual. MHC sequences were aligned manually using Se-Al Version 2.0a11 (available at http://evolve.zoo.ox.ac.uk/software.html?id=seal). Sequences were designated as different alleles if they were encountered more than once and in multiple clones. Sequences differing by one or two base pairs from previously designated haplotypes were not designated as new alleles unless they were encountered multiple times, as they were presumed to be an artifact of PCR. Nomenclature of alleles followed Klein *et al.* (1990). The reason for this conservative approach to allele designations is that MHC sequences are prone to formation of artifactual, mosaic sequences during the cloning procedure (Borriello & Krauter 1990; L' Abbe *et al*. 1992).

Statistical Analysis- Microsatellites

Microsatellite data was checked for errors using MICROSATELLITE TOOLKIT (add-in for Microsoft Excel written by S. Park, available at http://animalgenomics.ucd.ie/sdepark/ms-toolkit/). Nei's unbiased genetic diversity (Nei

1987), observed heterozygosity and allele frequencies were obtained using this program. The computer program Microchecker (van Oosterhout *et al.* 2004) was used to examine the data for scoring errors due to stuttering, presence of large allele dropout and null alleles. For each microsatellite locus and population, allelic richness (A_R), total number of alleles (N_a) and inbreeding co-efficients (F_{IS}) were obtained using FSTAT version 2.9.3.1 (Goudet 1995). Allelic richness was calculated using the methods described Petit *et al.* (1998). This method allows the number of alleles to be compared among populations independently of sample size (Leberg 2002) and is based on the smallest number of individuals typed for any locus. The computer package ARLEQUIN (Schneider *et al.* 2000) was used to assess whether there were significant departures from Hardy-Weinberg equilibrium using the procedure of Guo and Thompson (1992). Global tests for linkage disequilibrium (non-random association of loci) were conducted for all pairs of loci using FSTAT. Bonferroni (Rice 1989) correction was applied to account for multiple simultaneous tests. Weir and Cockerham's (1984) *F*-statistics were calculated using ARLEQUIN (Schneider *et al.* 2000) to determine the magnitude of differences between samples collected at different localities. F_{ST} is the standardized variance in allele frequencies between populations and is the most commonly used measure of genetic distance between populations. P-values for all statistics were generated using a bootstrapping method (10,000 permutations).

Mt-DNA- ND4

Estimates of unbiased gene diversity (h) and nucleotide diversity (π) were obtained using ARLEQUIN Version 3.0 for mitochondrial DNA data. Allelic richness was calculated using FSTAT. ϕ-statistics were calculated from mt-DNA data using ARLEQUIN (Excoffier *et al.* 1992). ϕ-statistics are equivalent to F-statistics (Weir & Cockerham 1984), however they incorporate allele frequencies and evolutionary distances between haplotypes.

Phylogenetic Analysis- MHC

MHC sequences were aligned manually using Se-Al Version 2.0a11 (available at http://evolve.zoo.ox.ac.uk/software.html?id=seal). The computer program TCS (Clement *et al.* 2000) was used to construct a statistical parsimony network among MHC alleles using the method of Templeton *et al.* (1992). We aligned Rio Grande silvery minnow MHC sequences to published MHC sequences from representatives of the cyprinids

including common carp, Lake Tama African 'large' barb, carp bream and zebrafish. Phylogenetic trees were reconstructed using Bayesian analysis as implemented in MrBayes (Huelsebeck and Ronquist 2001). For Bayesian analysis the General Time Reversible Model + I + Γ was used and model parameter were treated as unknown variables with uniform priors and were estimated during the analysis. Random starting trees were used and two simultaneous analyses were run for 1 x 10^7 generations sampling every 100^{th} generation from the chain. Four chains (three hot and one cold) were run simultaneously. The first 25% of trees were discarded as burn-in samples and the remaining trees were used to construct a majority rule consensus tree. Bayesian posterior probabilities were obtained for the remaining tree. Posterior probabilities above 95% are considered strong support for a clade (Wilcox *et al.* 2002).

MHC- *Tests of Selection*

To determine whether there was evidence of selection and the type of selection (positive [beneficial mutations increase in frequency in the population], purifying [deleterious alleles decrease in frequency in the population], or neutral [i.e., no evidence of selection]) sequences were examined at the amino acid level. If MHC sequences are evolving neutrally, the ratio of non-synonymous (causes an amino acid substitution) (d_N) to synonymous (does not result in an amino acid substitution) (d_S) will not differ significantly from one. If there is positive selection, d_N with be greater than d_S, whilst for purifying selection, d_N will be less than d_S. We conducted Z-test of selection as implemented in MEGA v. 3.1. Ratios of d_S to d_N were estimated for sites presumed to be involved in peptide binding and for non-peptide binding sites. Designation of peptide binding sites were based on comparisons to human HLA three dimensional structure (Brown *et al.* 1993) following Dixon *et al.* (1996) and Ottova *et al.* (2005; 2007) because peptide binding sites have not been determined specifically for fish, including cyprinid fishes. Ratios of d_S to d_N were estimated across all MHC alleles identified and within each of the major allelic groups.

Association between MHC and parasite diversity

Scatter plots were generated to examine the relationship between sampling locality and genetic and parasite diversity measures including allelic richness (Mt-DNA and microsatellites), total number of MHC alleles, average number of parasite species and average level of infection of individuals. Non-parametric Spearman's rank correlation was used to test for associations

between MHC diversity (measured by total number of alleles observed irrespective of loci), total number of allelic groups represented (an allelic group was defined as a distinct lineage as determined by phylogenetic analysis) and parasites (measured by number of species observed per individual) using the computer package SPSS. For comparisons between the genetic data and parasites only gill parasite data was used. Allelic groups were DAB1, DAB1(2) and DAB3. The designation of these groups was based on the results of phylogenetic analysis. Intensity of infection was obtained per fish by categorizing abundance estimates: 0 (uninfected), 1 (less than 10 individuals of a parasite species), 2 (less than 50 individuals of a parasite species), 3 (more than 50 individuals of a parasite species). To obtain an overall estimate of the level of infection across all parasite species per individual, category values were summed (hence level of infection could range from 0 to 15 given a total of five parasite species).

Results

Microsatellite Diversity

All measures of genetic diversity calculated from microsatellite DNA data were similar between samples collected at each locality in 2006 (the only exception was WJR06-464 where fewer individuals were collected). In 2006 allelic richness was the greatest in the sample WJR06-462 (A_R = 9.363) while observed heterozygosity was highest in the sample SRD06-45 (H_O = 0.738) (Table 2). In 2008, all measures of genetic diversity were similar between localities. Allelic richness was slightly lower in the sample WJR08-814 (A_R = 9.586). In 2008 observed heterozygosity ranged from 0.659 to 0.720 (Table 2). In 2006 there were 10 departures from Hardy-Weinberg equilibrium whilst there were 13 deviations in 2008 from 42 comparisons. All of these were explained by deficiencies of heterozygotes. There was no evidence of linkage disequilibrium between pairs of microsatellite loci.

Pairwise F_{ST} was calculated between samples collected at six different localities on the Rio Grande (Table 3a). In 2006, F_{ST} values were very small and not significantly different from zero (at nominal α = 0.05). In 2008, there were six significant comparisons from 21 comparisons after Bonferroni correction was applied.

MtDNA Diversity-

In 2006 sequence data for partial mitochondrial DNA ND4 gene (295 base pairs) was obtained for 163 individuals allowing eight haplotypes to be identified. In 2008 sequence

Table 2. Summary statistics by collection locality for 2006 and 2008. Sample size (*N*), number of alleles (N_a), allelic richness (A_R) expected heterozygosity (H_E), observed heterozygosity (H_O), and average weighted inbreeding co-efficient (F_{IS}), gene diversity (*h*) and nucleotide diversity (π) are given. For MHC sample size (*N*), number of alleles (N_a) are given for DAB1-DAB1(2) and for DAB3.

data was obtained for 158 individuals revealing eight haplotypes. In all populations, haplotype A was the most prevalent. In 2006, three to seven haplotypes were identified per locality and in 2008 four to six haplotypes were seen at each locality.

In both 2006 and 2008 one significant value of Φ_{ST} was identified between WJR06-462 and WJR06-466 (F_{ST} = 0.079, P = 0.0264) and between WJR08-813 and WJR08-816 (F_{ST} = 0.0908, P = 0.0371) (Table 3b). After Bonferroni correction (Rice 1989) for multiple comparisons neither of these remained significant.

MHC Diversity- Overview

Two-hundred and seventy-four base pairs of sequence data encompassing 91 codons of the exon two region of MHC Class II beta region (the full length of exon 2 is 95 codons). Conserved cysteine residues (which are involved in the formation of di-sulfide bridges) and N-linked glycosylation sites were identified based on comparison to other published cyprinid sequences. These conserved sites could be identified in all of the MHC alleles observed in Rio Grande silvery minnow. Seventy-two unique haplotypes were identified among the 252 individuals. Most haplotypes were rare with only ten and eleven haplotypes present in more than 5% of individuals in 2008 and 2006 respectively (Figures 1a and 1b). In 2008, allele Hyam-DAB3*06 was present in more than 10% of individuals; an increase in the frequency in 2006. Eighteen alleles were identified that had a single codon deletion at position 72 (numbering based on Ottova *et al.* 2005). These alleles all belonged to the DAB1(2) group (see section below on phylogenetic analysis). A single haplotype belonging to the DAB1 group had a deletion at this position.

Phylogenetic Analysis

Bayesian analyses revealed two highly divergent clusters of MHC alleles. One of these was similar to DAB1 group of alleles identified previously in *Danio rerio*, *Cyprinus carpio*, *Barbus intermedius* (Ono *et al.* 1993). The other group was more similar to the DAB3 alleles (van Erp *et al.* 1993) previously described in other members of the family Cyprinidae than to DAB1 alleles identified in Rio Grande silvery minnow (Figure 2). The DAB3 group of alleles identified in Rio Grande silvery minnow formed monophyletic groups with *D. rerio*, *C. carpio*, *B. intermedius* DAB3-DAB4 alleles (100% posterior probability). Relationships among the Hyam-DAB3 alleles were poorly resolved. In addition to the DAB3 group of alleles, two other allelic groups were identified in Rio Grande silvery minnow that each had high to moderate support. The most basal

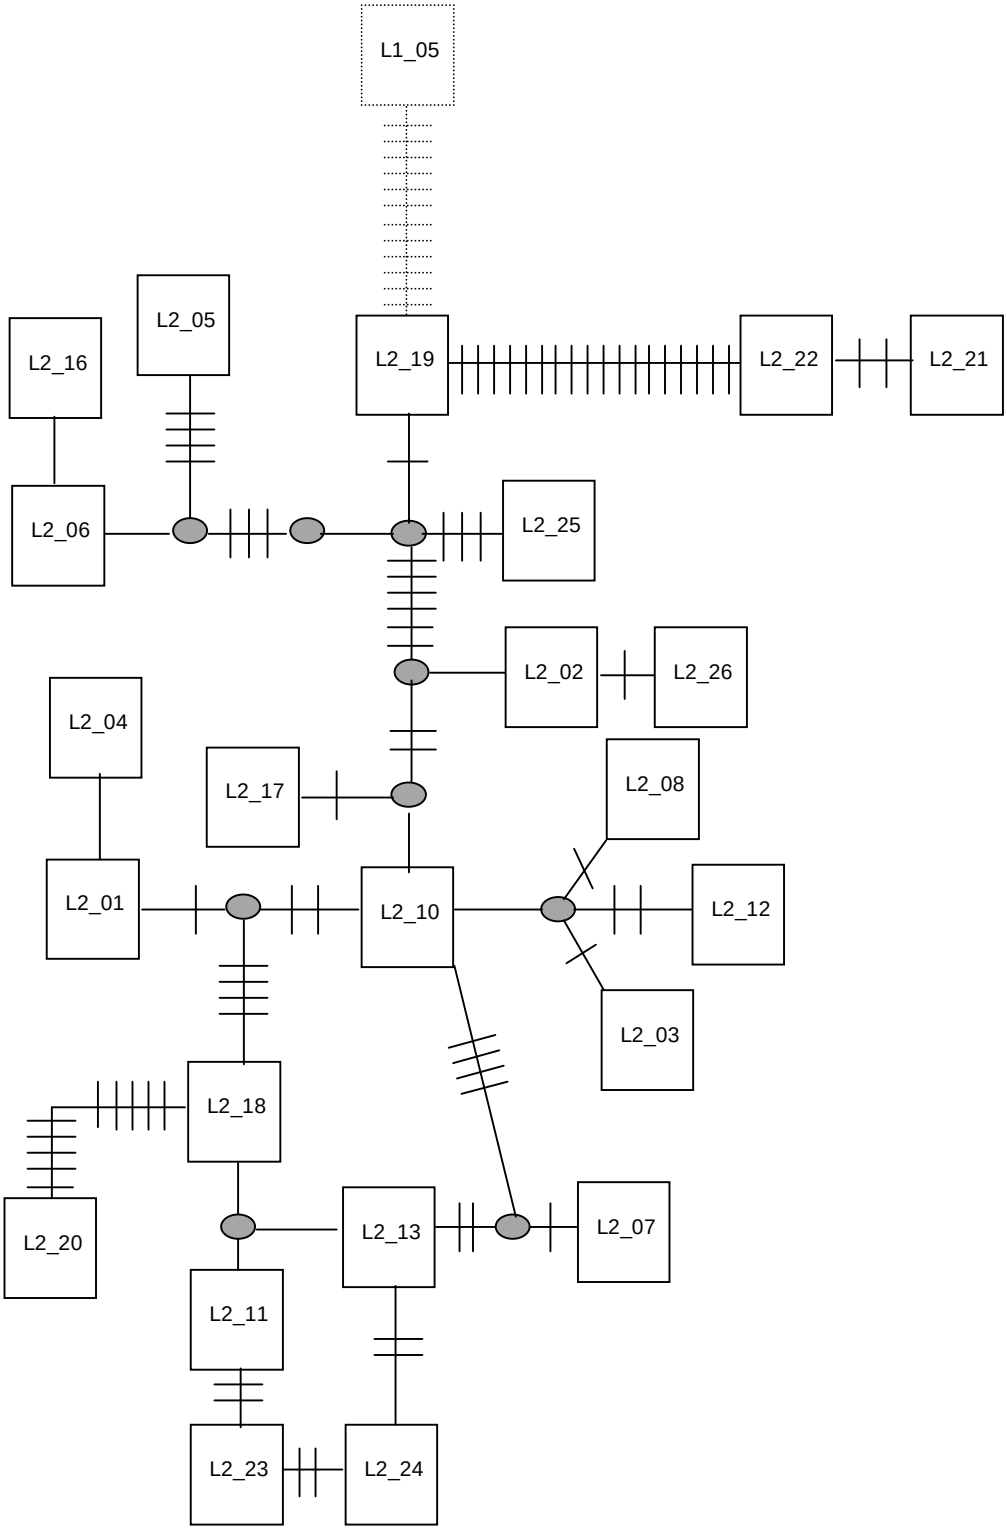

Figure 3a. Statistical phylogenetic network of DAB1 and DAB1(2) haplotypes identified in Rio Grande silvery minnow. Ovals and bars represent single nucleotide changes among haplotypes (indicated by boxes). Haplotype Hyam-DAB1*5 is shown on both pages and links the networks.

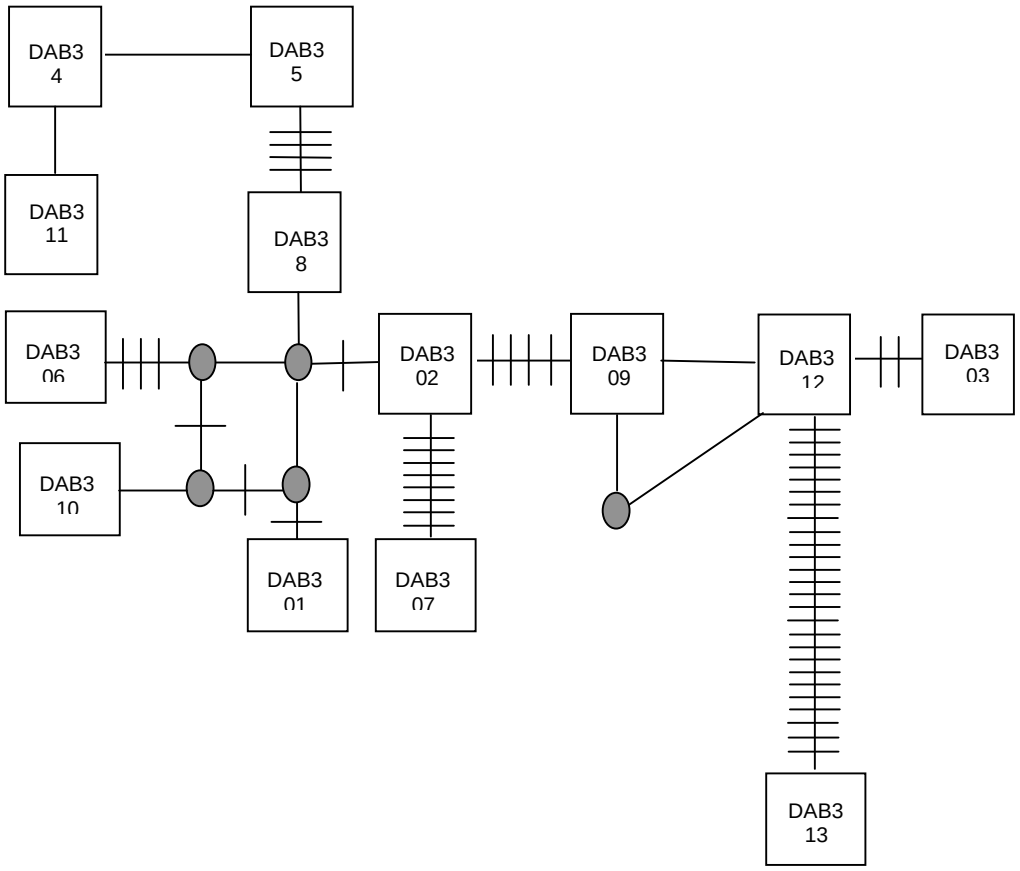

Figure 3b. Statistical phylogenetic network of DAB3 alleles identified in Rio Grande silvery minnow. Ovals and bars represent single nucleotide changes among haplotypes (indicated by boxes).

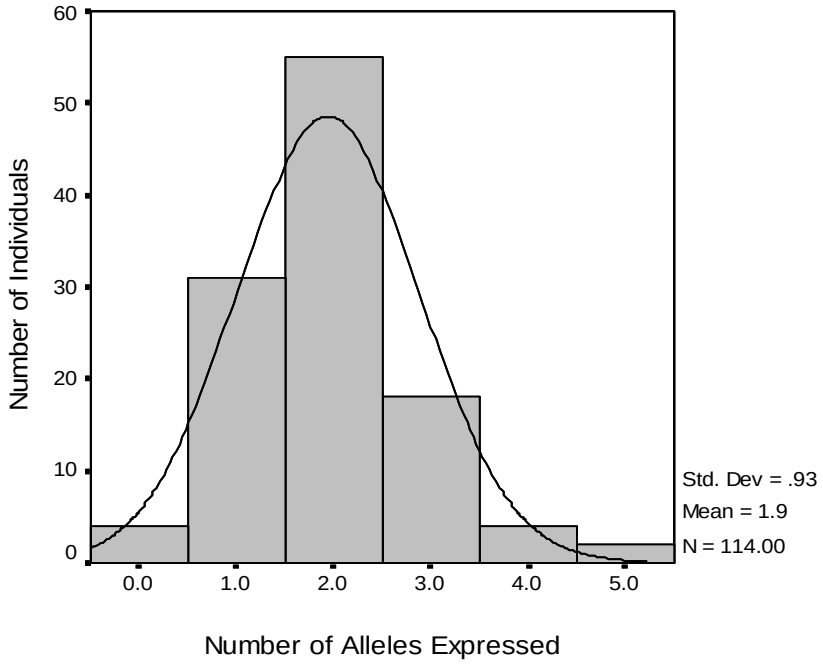
of the silvery minnow DAB1 groups included 22 alleles (80% posterior probability). The next group contained 55 alleles (61% posterior probability). The position of 10 DAB1 alleles was less well resolved with respect to these well-supported groups. The last of these groups was DAB1(2) (100% support), containing 25 different alleles which had 100% posterior probability support. The relationships identified by the statistical phylogenetic networks were consistent with the Bayesian results. Statistical phylogenetic networks demonstrate the high number of nucleotide substitutions among haplotypes within both the DAB1 and DAB1(2) groups (Figure 3a-b). In 2006, eight haplotypes were identified within the DAB3 group from 274 base pairs of sequence. In 2008, seven haplotypes were identified belonging to this group. Haplotype Hyam-DAB3*13 was very distinct from the other DAB3 alleles. Within this group DAB03*06 was the most frequently encountered allele in 2006 and in 2008. Divergence among the DAB3 alleles is much less than either of the DAB1 groups.

Evidence of Selection

When all sites and all alleles were considered, neutrality was rejected in favor of positive selection (Table 4). This was the case when only peptide binding sites and non-peptide binding sites were considered, and when all DAB1 alleles were considered. Interestingly, neutrality could not be rejected for DAB3 sequences when only peptide binding sites were considered but there was evidence of positive selection when all sites were considered and for non-peptide binding sites. For consideration of DAB1(2) alleles only, positive selection was evident when all sites were included but not when data was partitioned into sites involved with peptide binding or non-peptide binding.

MHC Diversity- Individuals and Allelic Groups

Individuals expressed alleles that belonged to one, two or three different allelic groups. In 2006, the maximum number of alleles identified per individual was five and in 2008 was it was four alleles. The mean number of alleles expressed per individual was 1.9 (Std. Dev. = 0.93) in 2006 and in 2008, the mean was 1.4 (Std. Dev.= 0.90) (Figure 4). Based on the phylogenetic analysis of alleles, individuals could be placed into the following groups: 1) individuals that expressed one or multiple alleles from a single allelic group [DAB1, DAB1(2) or DAB3]; 2) individuals that expressed one or multiple alleles from multiple allelic groups [DAB1 & DAB1(2); DAB1 & DAB3; DAB1(2) & DAB3] and 3) individuals that did not express alleles (or expression was not detected) in any allelic group. In 2006, four individuals were identified that did not appear to express (or expression was not detected) any MHC allele. RNA may have been degraded in



these samples. Using genomic DNA as template however, a PCR product was obtained for each of these individuals. In 2008, we could not determine MHC alleles for 23 individuals. Amplification of MHC was either unsuccessful due to absence of MHC expression or due to degradation of RNA or in some cases amplification was successful but sequence was not obtained. In 2006 and 2008 around 5% of fish expressed alleles representing each of the three allelic lineages. In 2006 the majority of fish (57%) expressed alleles belonging to two different groups, whilst 34% expressed alleles belonging to a single group. In 2008, the majority of individuals expressed alleles belonging to two allelic groups (59%) whilst 43.1% expressed alleles from a single group. In 2006 and 2008, 96% of individuals expressed alleles belonging to the DAB1- DAB1(2) group. In 2006 alleles belonging to the DAB3 group were only detected in 10.5% of individuals and only a single allele per individual (i.e. all individuals were homozygous) was identified within this allelic group. In 2008, we identified alleles from this group in 23% of individuals.

The average number of amino acid substitutions within each of the main allelic groups was 14.191 (SE = 1.936) substitutions for DAB1 alleles, 9.383 (SE = 1.558) among DAB1(2) alleles and 9.244 (SE = 1.757) among DAB3 alleles. There was an average of 20.520 (SE = 2.853) amino acid substitutions between the DAB1(2) group of alleles and the DAB1 group, whilst between these groups and the DAB3 group there were 46.244 (SE = 4.226) and 46.597 (SE = 4.310) amino acid changes, respectively. The number of amino acid changes between all Rio Grande silvery minnow the three DAB groups of alleles and outgroup alleles was 42.218 (DAB1), 42.391 [DAB1(2)] and 34.308 (DAB3).

Association between MHC and parasite diversity

In 2006, no correlation was found between the number of MHC alleles or the number of allelic groups and parasite diversity or intensity of infection (Table 5), nor was there an association between MHC and bacterial diversity. Spearman's Rho was significantly positive (after Bonferroni correction) for comparisons between populations (sampling locality) and parasite diversity ($rho = 0.341$, $P < 0.0001$), the number of MHC alleles identified per fish and the number of allelic groups ($rho = 0.195$, $P < 0.0001$) and between the parasite diversity and infection intensity. In 2008, Spearman's Rho was significantly negative for comparisons between collection locality and parasite diversity and infection intensity and for the comparison between parasite diversity and bacterial diversity. Spearman's Rho was significantly positive for the comparison of collection locality and bacterial diversity.

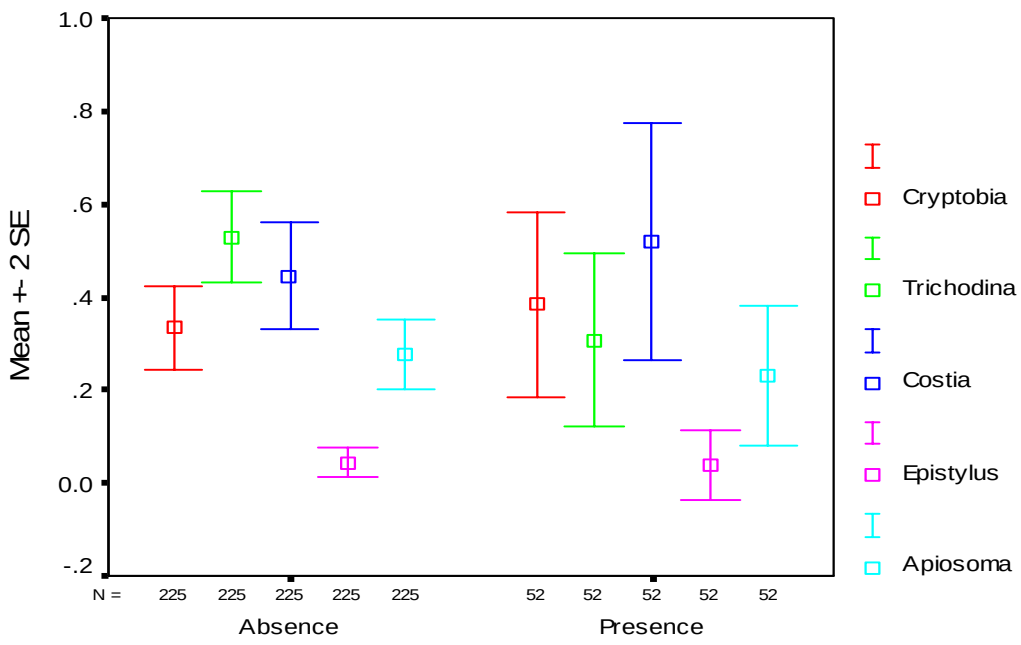
Error bar plots of the mean level of infection in fish with the presence or absence of the five most common alleles were constructed (2006 and 2008 data were pooled). These suggested that there may be significant associations between particular alleles and parasites (Figure 5a-e). The expression of Hyam-DAB1*05 was associated with lighter *Costia* spp. Infection, whilst expression of Hyam-DAB2*06 was associated with heavier *Costia* spp. infection. Expression of Hyam-DAB1*13 was associated with heavier *Apiosoma* infection. No relationship was detected between presence or absence of Hyam-DAB1*03 or Hyam-DAB2*04 and infection by a particular species.

Relationship of sampling locality, parasites and genetic diversity- 2006

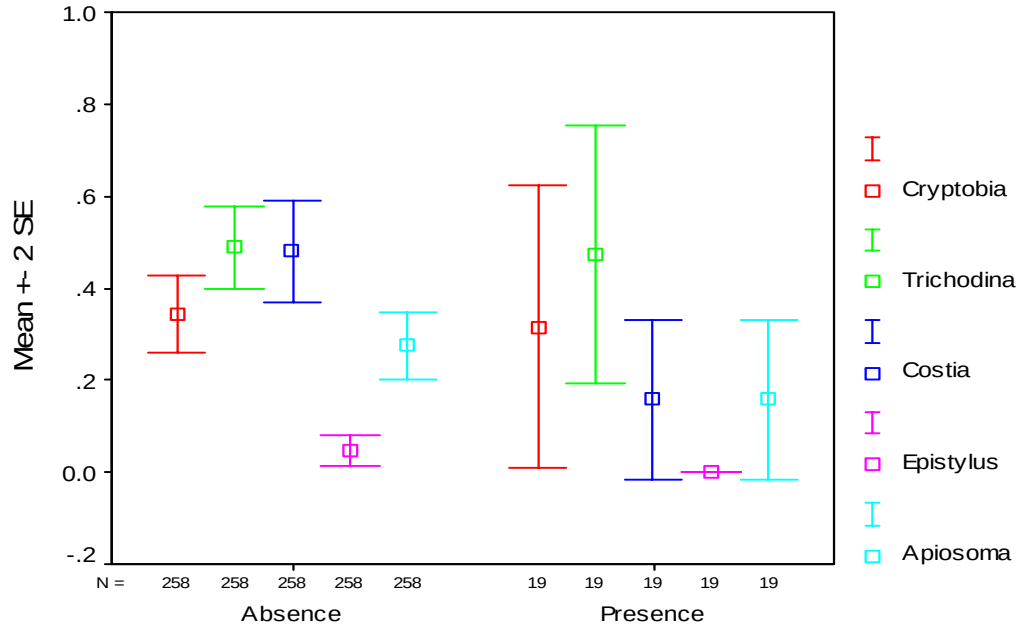
There was no noticeable difference among sampling localities in the amount of neutral genetic diversity (measured at the mtDNA-ND4 locus and across microsatellite loci) (Figure 6a). In contrast, there were more alleles expressed at MHC Class IIβ in fish collected from Bernalillo (WRJ06-468) and Alameda (WRJ06-466) when compared to fish collected from the southern sampling localities (La Joya and San Antonio). There were no strong trends in the number of parasite species or the level of infection between sampling localities. Nevertheless, overall level of infection appears to be higher in fish collected from the northern sites, whilst more parasite species were found on fish collected from Los Lunas (WJR06-462) and La Joya (WJR06-461). Fish collected from Los Padillas had the highest average level of infection.



Relationship of sampling locality, parasites and genetic diversity- 2008

In 2008, there was no difference in the amount of neutral genetic diversity as measured by allelic richness and total number of ND4 alleles among collection localities (Figure 6b). There were also no clear trends in the number of MHC alleles detected and collection locality. There was a striking trend in the average number of parasite species found on individuals by collection locality, with few species and very low infection levels at the two most northern sites (Bernallilo and Alameda), moderate infection levels and nubmber of species at Los Padillas and higher numbers of species and levels of infection on fish from Los Lunas, La Joya and Los Padillas.

Discussion



The goals of this study were to describe genetic variation in the endangered Rio Grande silvery minnow at loci that form a crucial component of the adaptive immune system and

to examine the relationship between this genetic variation and fish pathogen data. Major findings of this study include: i) identification of three evolutionarily divergent lineages of MHC Class IIβ alleles in Rio Grande silvery minnow; ii) differences in selective regimes between allelic groups, with evidence of strong selection in DAB1 and DAB1(2) groups; iii) retention of high levels of MHC Class IIβ allelic variation; iv) spatial differences in the amount of MHC Class IIβ diversity; v) no correlation between MHC Class IIβ and parasite diversity measures and vi) some evidence of association between particular alleles and presence or absence infection with particular pathogens. This study also includes the first description of MHC Class IIβ in a North American cyprinid fish and is one of only a handful of wild population-level studies that simultaneously compare MHC diversity and fish parasite communities.

Three divergent lineages of MHC Class IIβ alleles were identified in Rio Grande silvery minnow and two are highly homologous with allelic groups previously described in cyprinids (DAB1 and DAB3) (Ono *et al.* 1992; Graser *et al.* 1996; Sultmann *et al.* 1994; Ottova *et al.* 2005). The other allelic group [DAB1(2)] falls within the DAB1 group. Whether or not these lineages of alleles represent alleles of a single locus or are alleles of different loci is yet to be resolved (Ottova *et al.* 2005) and is complicated by the different ploidy (the number of homologous sets of chromosomes) levels in cyprinids. For example, the zebrafish and members of the Leuciscinae (includes North American cyprinids) are diploid (two sets of chromosomes), common carp is tetraploid (four sets of chromosomes) whilst the African ‘large’ barb is hexaploid (six sets of chromosomes). In the latter case, if there was a single heterozygous locus, the maximum number of alleles would be six (one allele per chromosome). With each additional locus, the number of alleles possible would double. The MHC sequences obtained during this study share homology with sections on zebrafish chromosome 8 (two distant locations) and to a single region on chromosome 13. DAB sequences identified in Rio Grande silvery minnow could therefore represent two paralagous sets of loci which has also been suggested for other cyprinid species (van Erp *et al.* 1996). Segregation studies performed in common carp suggested that there were two sets of paralagous loci (DAB1/DAB2 and DAB3/DAB4) that segregated independently (van Erp *et al.* 1996). Paralogous loci are clusters of genes that are at different chromosomal locations in the same organism but that are structurally similar indicating that they are derived from a common ancestral gene and have diverged following duplication or translocation by mutation, selection or drift. Additional data for Rio Grande silvery minnow exon 3 and

introns 2 and 3 (not presented) shows that exon 3 is highly divergent (between DAB1 and DAB3 alleles) while the introns cannot be aligned between these two allelic groups. This observation and the distant positions of DAB1 and DAB3 allelic groups in the phylogenetic tree, supports the notion that DAB1 and DAB3 may be distinct loci. The relationship between DAB1 and DAB1(2) is unclear, however the similarity of DAB1 and DAB1(2) exon 2, exon 3 and introns (data not included) suggest a more recent duplication event.

Selective regimes acting on each of the allelic lineages were variable which supports the possibility of multiple loci. There was evidence of positive, diversifying selection on all major groups of alleles including the Hyam-DAB3 group and the Hyam-DAB1 and Hyam-DAB1(2) groups with the majority of nucleotide substitutions resulting in amino acid changes. In several cases the d_N:d_S ratios were greater than three, a signature of strong positive selection. When the data was partitioned into sites thought to be involved with peptide binding and those that are non-peptide binding sites the results were more ambiguous. Hyam-DAB1 there was evidence for strong positive selection at peptide binding sites as well and non-peptide binding sites. For Hyam-DAB1(2) this was not the case and for Hyam-DAB3 only non-peptide binding sites appeared to be under positive selection. The designation of peptide binding sites in fish is based on the three dimensional structure of human HLA so it is possible that there are additional peptide binding sites in fish that are yet to be identified. Ottova *et al*. also considered the selective pressures acting on MHC allelic groups in Leucisinae and Cypininae and found evidence of positive selection on DAB3 for the former group, but on both DAB1 and DAB3 for the latter group. Ottova *et al.* (2007) suggests that DAB1 may have secondarily acquired function.

There are some puzzling features of Rio Grande silvery minnow DAB3 including the infrequency of transcription (and rarity of presence in genomic DNA) of DAB3 alleles (~10% of individuals) and the absence of any individuals with more than allele at this locus. A possible explanation for both of these observations is the presence of null DAB3 alleles at high frequencies in the population. A null allele is an allele that consistently fails to amplify and this may be because of mutations within the section of sequence where the PCR primer is designed to anneal. Alternatively there may be transcriptional regulation of expression whereby sequences are present in genomic DNA but not all are transcribed or alternatively, there may be inactivation of other MHC copies by codon deletions or accumulation of mutations, which would make the genes non-functional in

the immune response. The former has been demonstrated in polyploid species including the African 'large' barb (Kruiswijk *et al.* (2004), and the latter has been shown in the African clawed frog, *Xenopus* (Sato *et al.* 1993). We do not think that the former possibility is the case in Rio Grande silvery minnow, as DAB3 sequences from could not be amplified from the genomic DNA of any additional individuals. Van Erp *et al.* (1996) suggested that inheritance of MHC in cyprinids may not follow Mendelian rules.

We observed amino acid polymorphisms among alleles within the DAB3 group that were shared between divergent cyprinid lineages (e.g. Rio Grande silvery minnow, common carp and carp bream). These polymorphisms were often ones that distinguish DAB1 and DAB3 lineages. Sharing of residues may be a result of convergent evolution or may be a result of shared ancestry with maintenance of ancestral polymorphisms through selection (Hughes *et al.* 1994). In mammals, it has been suggested that there is an upper time limit (separations of 30-40 million years) for the sharing of ancestral MHC polymorphisms (Takahata & Nei 1990; Hughes *et al.* 1994). The family Cyprinidae is roughly 40 million years old (Zardoya & Doadrio 1999) and so is at the upper limit of the time scale suggested for conservation of shared polymorphism in mammals.

The Rio Grande silvery minnow population is characterized by high MHC Class IIβ diversity with 72 alleles recognized among 254 individuals. Taking the differences in sample sizes between studies into account, this diversity is comparable to the one cyprinid species for which limited population level data is available. The recent study of the carp bream identified 32 different exon 2 sequences (DAB1- 17 alleles, DAB3- 15 alleles) among 20 individuals (Ottova *et al.* 2007). A smaller dataset obtained for two species of zebrafish revealed 36 alleles (based on intron 1 and exon 2 sequences) from 28 fish (Graser *et al.* 1996). A similar comparison across four species of African 'large' barb recognized 29 DAB1 alleles among 16 individuals (Kruiswijk *et al.* 2005). Among salmonids, Dorschner *et al.* (2000) identified 42 MHC Class IIβ alleles among 74 individual lake trout and 88 alleles in steelhead trout (Aguilar & Garza 2006). However, high level of diversity appears to be the exception within this group with only nine alleles identified from 120 Atlantic salmon (Langefors 2001), 11 DAB1 alleles identified among 13,000 sockeye salmon and in Gila trout only five alleles were identified from 142 individuals assayed (Peters and Turner, In Press). Differences in habitat, environment and exposure to pathogens may account for differences in MHC diversity among cyprinid and salmonid taxa. For example, Rio Grande silvery minnow inhabits a warm-water system where parasites and pathogens are more prevalent than in cold-water

mountain streams. Unfortunately there is no MHC data from other Southwestern cyprinid taxa with which to compare our silvery minnow data, so we do not know if the level of MHC diversity in this species is 'normal'. In addition to large numbers of alleles, the level of divergence among DAB1 alleles is generally high in silvery minnow. Large divergence among alleles could be explained by either rapid mutation rate or long persistence time of allelic lineages (Klein *et al*. 1993). Findings of Grase et al. (1996) support the latter explanation.

The high level of MHC Class IIβ diversity seen in Rio Grande silvery minnow is in stark contrast to low levels of variation (in terms of number of alleles and the divergence between them) at the mtDNA ND4 locus. We have screened in excess of 3000 Rio Grande silvery minnow for mtDNA ND4 variation and only identified 14 closely related ND4 alleles (Osborne et al. 2005). The low level of mtDNA diversity is indicative of a severe historical population bottleneck in Rio Grande silvery minnow. Furthermore the contemporary population is characterized by a small genetic effective size (N_{ev}~100 Turner and Osborne unpublished data). Differences in levels of variability between the different markers (mtDNA, microsatellites and MHC) are likely due to differences in selective pressures, ploidy levels, mutation rates and inheritance patterns.

An unexpected result of this study was the difference in the number of MHC Class IIβ alleles expressed at each of the localities, with fewer alleles expressed by fish in southern sites in 2006. In 2008 however there were similar numbers of MHC alleles detected at each of the localities with the highest number seen at La Joya. Data from neutral markers (microsatellites and mtDNA) allow genetic drift to be discounted as a driving factor behind this observation, as we see no differences in number of alleles identified at these loci. In addition, frequencies of mtDNA-ND4 haplotypes and microsatellite alleles do not differ significantly among collection localities, which is consistent with high gene flow between the Rio Grande silvery minnow sampling localities (Osborne *et al.* 2005). Rio Grande silvery minnow produce non-adhesive pelagic eggs that are subject to drift with river currents (Platania and Altenbach 1998, Osborne *et al.* 2005) allowing homogenization of the population. Although there are water diversion structures that preclude upstream movement, management activities, particularly augmentation of the wild population with captively reared fish, also results in mixing of the population.

There have only been a handful of studies that have considered the relationship between MHC and pathogens in fish. From these studies, three conclusions have been

drawn: i) survival to infection and susceptibility may be associated with specific MHC alleles (e.g. Langefors 2001); ii) resistance or survival from infection may be associated with increased MHC heterozygosity (Arkush *et al.* 2002; Hedrick *et al.* 2001b) or; iii) parasites may drive MHC variability but there is an optimal number of MHC alleles within an individual (Wegner *et al.* 2003). In Rio Grande silvery minnow we were only able to test for a relationship between the number of MHC alleles and number of allelic groups per fish as heterozygosity and nucleotide diversity could not be calculated (because alleles could not assigned to loci). A significant association between the number of MHC Class IIβ alleles expressed and the number of parasites infecting an individual was not seen. There was also no relationship observed between the number of allelic groups represented (within individuals) and parasite diversity measures (number of species and overall level of infection). This is concordant with the results of Ottova (2007). In fact, in carp bream, expression of two alleles from a single allelic type was associated with higher ecto-parasite loads (Ottova *et al.* 2007). They also found that increased nucleotide diversity measured at alleles of a single type was associated with higher abundances of the ecto-parasites *Dactylogyrus* spp. and *Ergasilus* spp., and that immunocompetance was lower in these fish.

Although not rigorously tested statistically (because of relatively small sample sizes), there did appear to be an association between expression of Hyam-DAB1*05 by Rio Grande silvery minnow and lighter infection by *Costia* spp. There also appeared to be an association between the presence of Hyam-DAB1(2)*06 and heavier *Costia* spp. Infection and between presence of Hyam-DAB1*13 and heavier *Apiosoma* infection. If these relationships prove robust it would be the first report in a cyprinid fish of a specific association between an MHC allele and a parasite species. In carp bream no association was detected between expression of certain MHC Class IIβ alleles and resistance to specific parasites (Ottova *et al.* 2007). This was also true for the three-spined stickleback (*Gasterosteus aculeatus*) (Wegner *et al.* 2003). These species are characterized by large numbers of alleles that are generally present at low frequencies within the population. This combination of factors limits the power to test for correlations between parasite species richness and abundance and MHC diversity. Rio Grande silvery minnow MHC Class IIβ also has many alleles but most are present at low, so it is surprising that we see evidence of relationships between particular alleles and infection with particular parasites. There may also be effects of collection locality on these results.

In contrast to cyprinids, salmonids have a single MHC Class IIβ locus and few alleles present at high frequencies improving chances of detecting significant associations (Stet *et al.* 2002). The salmonid studies also selected particular pathogens *a priori* to test for association with MHC alleles (Miller *et al.* 2004; Grimholdt et al 2003). The ecto-parasites that were encountered on Rio Grande silvery minnow gills were all generalist, opportunistic pathogens that have direct life-cycles (i.e. no intermediate host). Klein & O'Huigin (1994) suggested that the immune system of hosts would be more likely to evolve in response to specific parasites than to generalists and hence MHC polymorphism should be more impacted by specific parasites. The relationship between the hosts immune system and parasites is also likely to be a dynamic one and immunity/susceptibility may also involve interaction between multiple alleles.

The relationship of parasites, hosts and their variation at MHC is determined by a long list of factors that include both biotic and abiotic features that are intertwined. Some of the factors that affect parasite abundance include the physiology and biological features of the host, chemical properties of the water, the age of the fish (and hence its size), diet of the host, size and connectivity of the habitat that the fish occupies (reviewed in Dogiel *et al.* 1961) and the history of co-evolution between host and pathogen. MHC is not only involved with immunity but in some species of fish these genes play a role in mate choice so there may be a tradeoff between these functions. The present study on MHC Class IIβ genes within the wild population of Rio Grande silvery minnow provides a crucial data set that will allow future investigations of the various factors that may drive diversity at MHC genes of this species.

Conclusions and Implications for Management

MHC variation in in Rio Grande silvery minnow is decoupled from microsatellite and ND4 variation. Further investigation of MHC Class IIβ genes in Rio Grande silvery minnow is required to understand the mechanisms that drive diversity at these genes.

Further research will involve trying to determine the number of MHC loci that are present in this species. This will allow more accurate measures of MHC diversity to be obtained. Coupling this information with increased sample size and more accurate measures of parasite load would improve our power to detect associations between MHC and parasite diversity. Variation in MHC allele frequencies among populations and the high number of rare MHC alleles argues for wide collection of broodstock for hatchery practices, or ideally collection of wild-caught eggs encompassing the geographic range

of the species. Further research is needed that seeks to understand whether there is: i) transcriptional regulated of allelic variation or; ii) regulation at the genomic level which would allow a deeper understanding of management implications of MHC variation in Rio Grande silvery minnow.
